ABSTRACT

We present a model for estimating horizontal ground motion amplitudes caused by shallow crustal earthquakes occurring in active tectonic environments. The model provides predictive relationships for the orientation-independent average horizontal component of ground motions. Relationships are provided for peak acceleration, peak velocity, and 5-percent damped pseudo-spectral acceleration for spectral periods of 0.01–10 sec. The model represents an update of the relationships developed by Sadigh et al. (1997) and includes improved magnitude and distance scaling forms as well as hanging-wall effects. Site effects are represented by smooth functions of average shear-wave velocity of the upper 30 m (V_{S30}) and sediment depth. The new model predicts median ground motion that is similar to Sadigh et al. (1997) at short spectral periods, but lower ground motions at longer periods. The new model produces slightly lower ground motions in the distance range of 10–50 km and larger ground motions at larger distances. The aleatory variability in ground motion amplitude was found to depend on earthquake magnitude and on the degree of nonlinear soil response. For large-magnitude earthquakes, the aleatory variability is larger than found by Sadigh et al. (1997).

ACKNOWLEDGMENTS

This study was sponsored by the Pacific Earthquake Engineering Research (PEER) Center's Program of Applied Earthquake Engineering Research of Lifelines Systems supported by the California Department of Transportation, the California Energy Commission, and the Pacific Gas and Electric Company.

This work made use of the Earthquake Engineering Research Centers Shared Facilities supported by the National Science Foundation under award number EEC-9701568 through the Pacific Earthquake Engineering Research Center. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect those of the National Science Foundation.

We would like to thank all of the members of the PEER-NGA project for many enlightening interactions. We would also like to thank Steve Day, Walt Silva, and Paul Somerville for providing us with ground motion simulation results that helped us in formulating our model. Some of the graphics in this report were prepared using R (R Development Core Team 2006).

1 Introduction

This report presents a ground motion model developed as part of the Pacific Earthquake Engineering Research Center's (PEER) Next Generation Attenuation model (NGA) project. This model is for estimating horizontal ground motion amplitudes caused by shallow crustal earthquakes occurring in active tectonic environments. Our model provides predictive relationships for the orientation-independent average horizontal component of ground motions. Relationships are provided for peak acceleration, peak velocity, and 5-percent damped pseudo-spectral acceleration (*PSA*) for spectral periods of 0.01–10 sec. The model is based on analyses of the PEER-NGA empirical strong-motion database (Chiou et al. 2008). We consider the model presented here to be an update of the set of models developed by Sadigh et al. (1997). As such, we have systematically reviewed the various aspects of the model (e.g., magnitude and distance scaling, site effects, style of faulting effect) and have introduced modifications to the formulation of Sadigh et al. (1997) to incorporate the results of both analyses of empirical data and numerical modeling of earthquake ground motions.

In the following, we first describe the empirical data used to develop the model. We then describe the development of the ground motion model formulation, followed by a description of the process used to define the model coefficients. Finally, we compare the model predictions with those obtained using Sadigh et al. (1997).

2 Empirical Database

The empirical data set used in this study was derived from the PEER-NGA database (Chiou et al. 2008; PEER-NGA flat file Version 7.2). In addition, we supplemented the PEER-NGA flat file with imputed values of missing metadata and with strong-motion data from the California ShakeMap system. These supplemental data, as well as data selection criteria, are discussed in this chapter.

2.1 SUPPLEMENTAL METADATA

The PEER-NGA flat file does not contain the full set of metadata for many of the recordings. The missing data of importance to the ground motion model developed in this study are the following: depth to top of rupture (Z_{TOR}), fault geometry and faulting mechanisms for smaller earthquakes, rupture distances for those earthquakes without published rupture models, and, for many sites, the average shear-wave velocity (V_{S30}) and sediment depth (defined as the depth to shear-wave velocity of 1 km/sec, $Z_{1.0}$). The missing values for these parameters were imputed (estimated) as follows.

2.1.1 Focal Depth, Fault Strike, Fault Dip, and Rake

The PEER-NGA database contains 41 earthquakes with missing parameters defining the characteristics of the earthquake rupture. These earthquakes are listed in Table 2.1 along with estimated values for the missing parameters. The missing values were estimated from other associated events such as the main shock or other aftershocks, or from the tectonic environment. For those earthquakes unassociated with other events, fault dips were assigned based on known or inferred mechanisms as follows, 90° for strike-slip, 40° for reverse (based on average value reported by Sibson and Xie 1998), and 55° for normal (generic value for normal faults and close

to the average of 54° for the normal mechanisms with known dips in the PEER-NGA database). Where the fault strike could not be inferred, it was assumed random. The comments in Table 2.1 indicate the basis for each estimate.

Table 2.1 Inferred mechanisms, hypocenter depths, fault strikes, and fault dips.

2.1.2 Rupture Distances and Source-Site Geometry

Of the 173 earthquakes in the PEER-NGA database, 110 do not have associated finite fault models that can be used to compute the standard measures of distance to rupture (e.g., rupture distance R_{RUP} and Joyner-Boore distance, R_{JB}) and the source-site geometry parameters such as hanging-wall and footwall positions and the source-site angle θ_{SITE} . The use of hypocentral distance, R_{HYP} , and epicentral distance, R_{EPI} , for R_{RUP} and R_{JB} , respectively, introduces a bias in the values as in most situations $R_{RUP} < R_{HYP}$ and $R_{JB} < R_{EPI}$, even for small events. The various geometry and distance measures for these earthquakes were estimated by simulating earthquake ruptures using the earthquake size and known or inferred information on the hypocentral depth, fault strike, fault dip, and rupture mechanism. Appendix B describes the simulation process. Figure 2.1 shows the ratios of R_{JB}/R_{EPI} and R_{RUP}/R_{HYP} for the 702 recordings from the 110 earthquakes, and indicates the magnitude of the bias that could be introduced by using R_{EPI} for R_{JB} and R_{HYP} for R_{RUP} . The analysis also provided estimates of the depth to the top of rupture, Z_{TOR} , and rupture width, W , for these earthquakes.

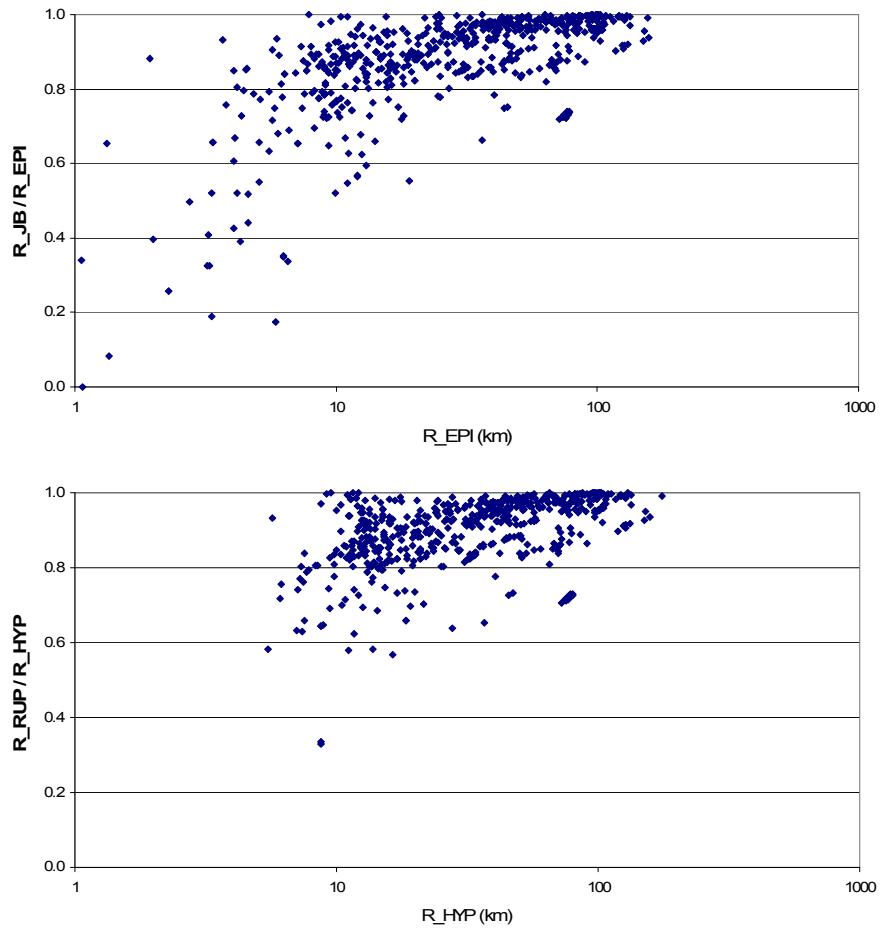

Fig. 2.1 Ratio of estimated values of R_{JB} and R_{RUP} to R_{EPI} and R_{HYP} for recordings from earthquakes without finite fault models in PEER-NGA database.

2.1.3 Site Average Shear-Wave Velocity

Approximately two thirds of the recordings in the PEER-NGA database were obtained at sites without measured values of shear-wave velocity. As part of the database compilation, empirical correlations between the surface geology and the average shear-wave velocity in the top 30 meters, V_{S30} , were developed (Chiou and others 2008). These relationships together with assessments of the surface geology from geologic maps and site descriptions were used to estimate values of V_{S30} at the sites without measured velocities. Additional analysis was performed as part of this study to improve the correlation between surface geology and V_{S30} for the Taiwan sites. This analysis is described in Appendix C.

Figures 2.2 and 2.3 show the measured (solid circles) and estimated (open circles) values of V_{S30} versus magnitude and distance, respectively, for the records in the PEER-NGA database.

Also indicated on the figures are the divisions of the NEHRP site categories A–E. The data distributions plotted in Figures 2.2 and 2.3 indicate that the PEER-NGA database is primarily a soil/soft rock database.

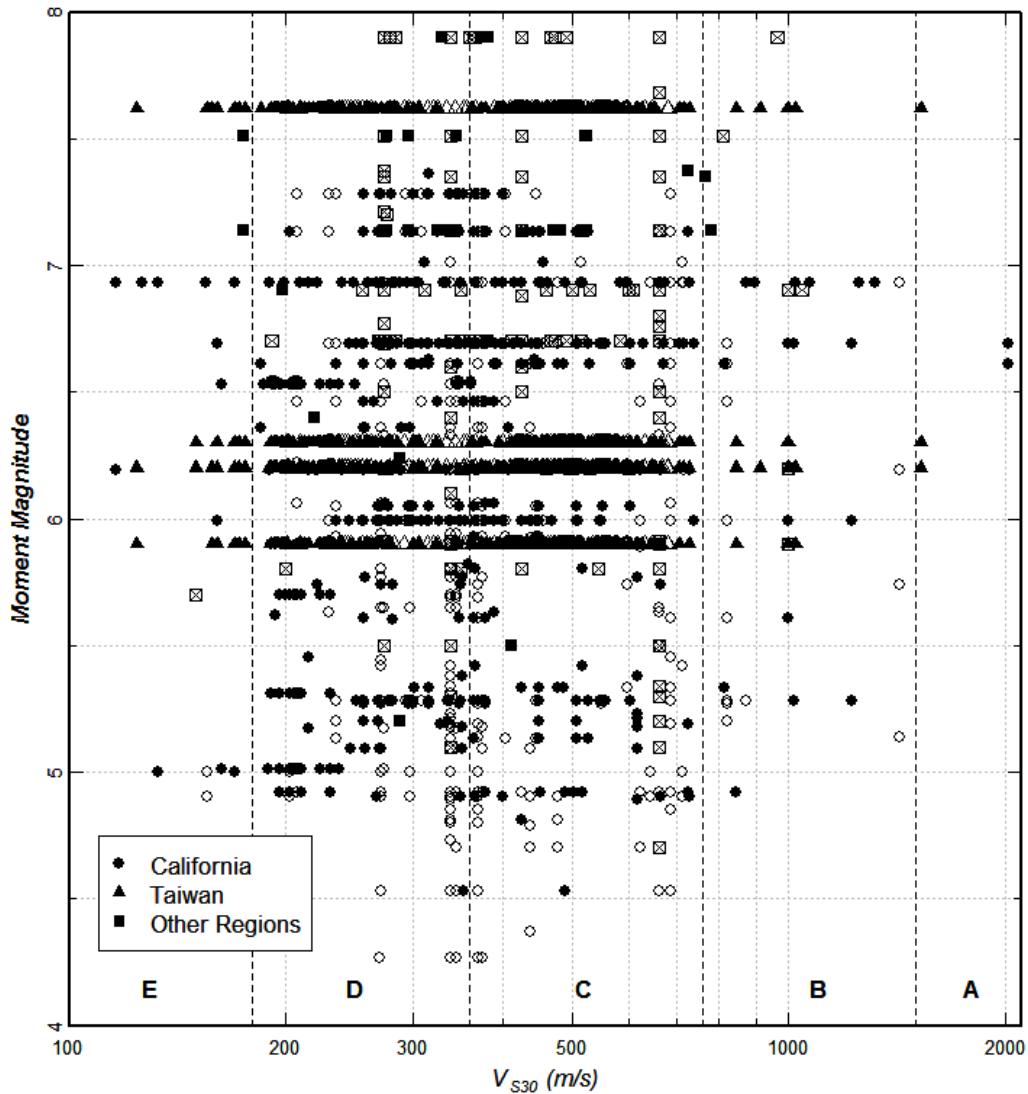

Fig. 2.2 V_{S30} -magnitude-region distribution of PEER-NGA recordings. Closed symbols indicate measured values, open symbols inferred values. NEHRP site classes are indicated along bottom edge.

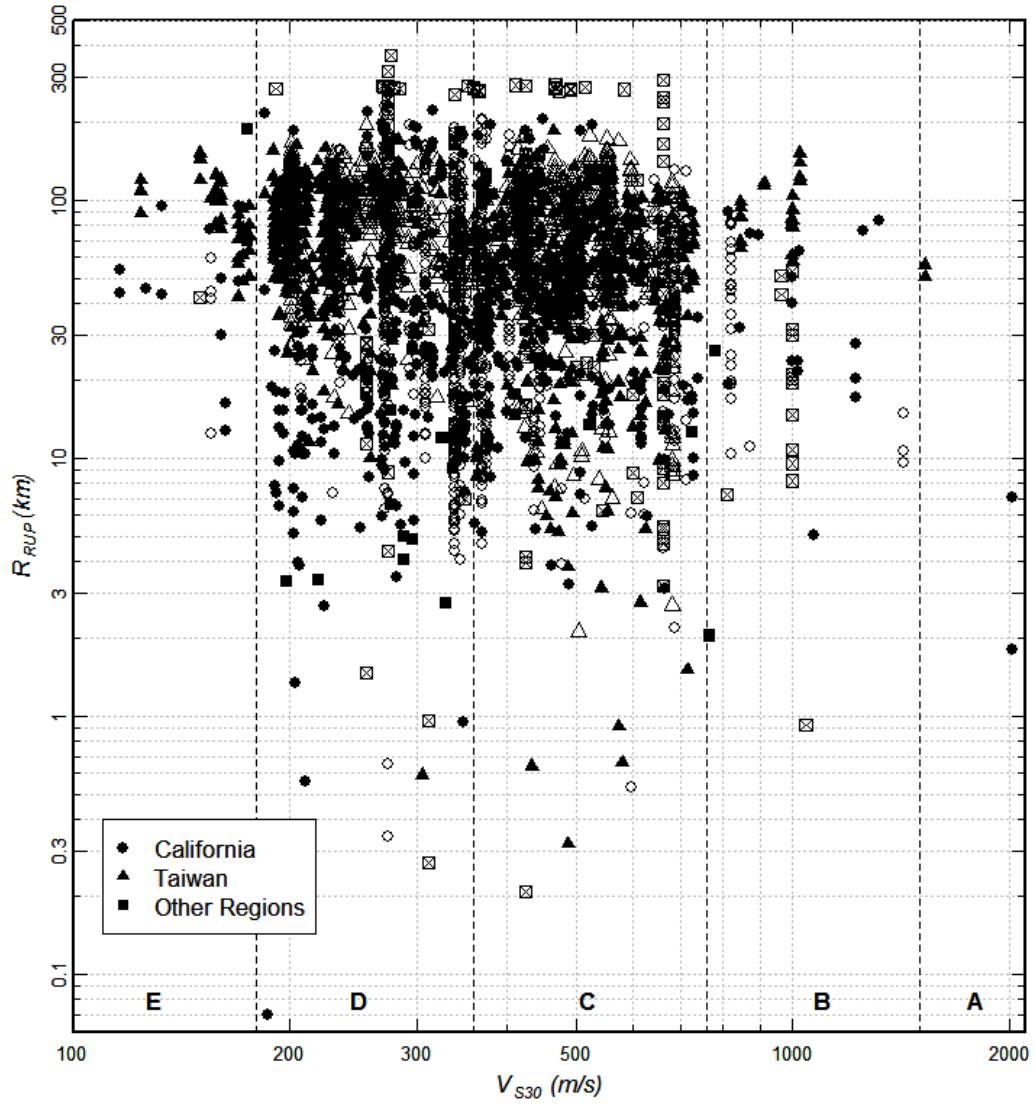

Fig. 2.3 V_{S30} -distance-region distribution of PEER-NGA recordings. Closed symbols indicate measured values, open symbols inferred values. NEHRP site classes are indicated along bottom edge.

2.1.4 Sediment Thickness

The thickness of the near-surface sediments is represented in our NGA model by the depth to a shear-wave velocity of 1.0 km/s, $Z_{1.0}$. These data are available in the PEER-NGA database for sites in the Southern California Earthquake Center 3-D (SCEC-3D) basin model (Magistrale et al. 2000), for sites in the USGS velocity model for the San Francisco Bay area (Boatwright et al. 2004), for sites in the Eel River basin (Graves 1994), and for sites where measured velocities reach this velocity horizon. Note that in our study we updated the $Z_{1.0}$ values from SCEC-3D

Version 2 to those from Version 4 (<http://www.data.scec.org/3Dvelocity/>). The newly determined V_P -density ratio used by Version 4 produces a new V_S model and hence new $Z_{1.0}$ value. Figure 2.4 shows the relationship between the two $Z_{1.0}$ values for southern California stations. Points on the line of slope 1.52 are sites affected by the new V_P -density ratio. Points off the sloping line are sites in areas such as San Bernardino valley and Salton trough where the V_S model has been improved in Version 4.

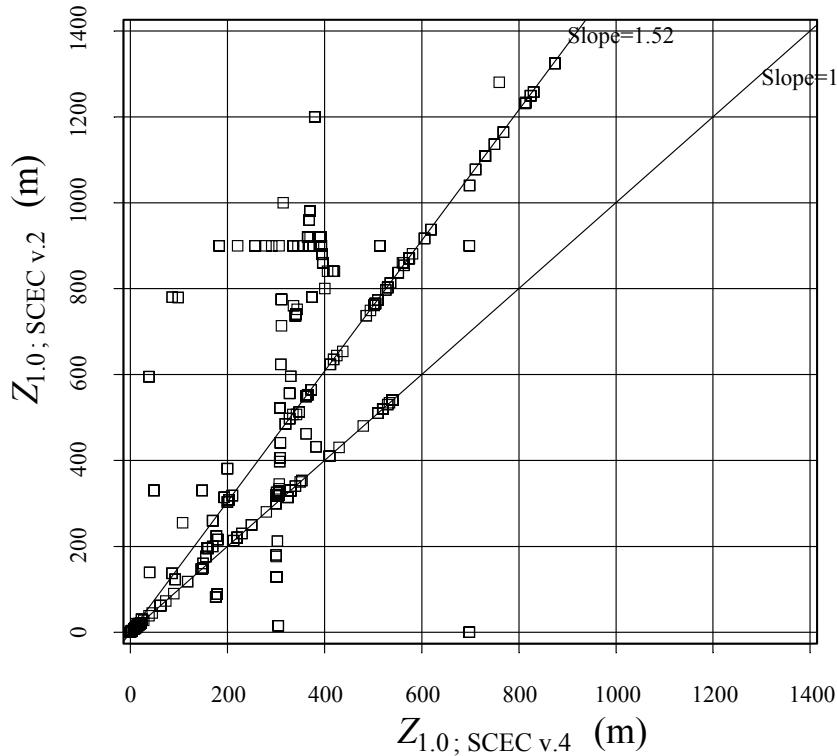

Fig. 2.4 Comparison of $Z_{1.0}$ values from Versions 2 and 4 of SCEC 3-D velocity model.

When $Z_{1.0}$ is not available, it was estimated through the following correlation with V_{S30} developed from the measured $(V_{S30}, Z_{1.0})$ data in the PEER-NGA database (Fig. 2.5):

$$\ln(Z_{1.0}) = 28.5 - \frac{3.82}{8} \ln(V_{S30}^8 + 378.7^8) \quad (2.1)$$

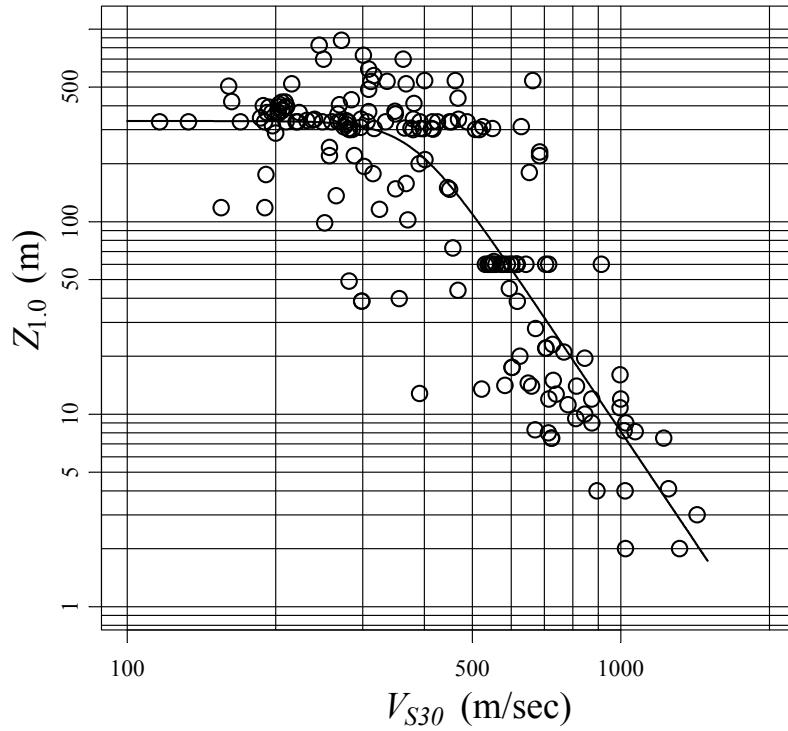

Fig. 2.5 Relationship between measured $Z_{1.0}$ and V_{S30} for sites contained in PEER-NGA database. Solid curve is the relation used to infer values of missing $Z_{1.0}$ data.

2.2 DATA SELECTION

The data set used in this study was selected from the PEER-NGA empirical strong-motion database. Our ground motion model was developed to represent free-field motions from shallow crustal earthquakes in active tectonic regions, principally California. Data from earthquakes that occurred in oceanic crust offshore California and Taiwan (Table 2.2) were excluded because ground motions from these types of events have been found to be more consistent with ground motions from the Wadati-Benioff zone (subduction intraslab) earthquakes than shallow crustal earthquakes (Geomatrix Consultants 1995). Data from the 1992 Cape Mendocino earthquakes were included because the source depth places the event above the likely interface location (Oppenheimer et al. 1993). Four 1997 northwest China earthquakes were excluded because of their moderate depths (≥ 20 km) and the very limited information about the events and their recordings. Data from the 1979 St. Elias earthquake were excluded because we interpret this earthquake to have occurred on a subduction zone interface based on its depth, dip, and location. Data from the 1985 Nahanni, Canada, and the 1992 Roermond, Netherlands, earthquakes were

included as these earthquakes are interpreted to have occurred at the boundary of stable continental regions (SCR) with active tectonic regions.

Table 2.2 Excluded earthquakes.

EQID	EQNAME	Comment
0003	Humboldt Bay	Gorda plate
0005	Northwest Calif-01	Gorda plate
0007	Northwest Calif-02	Gorda plate
0008	Northern Calif-01	Gorda plate
0011	Northwest Calif-03	Gorda plate
0013	Northern Calif-02	Gorda plate
0017	Northern Calif-03	Gorda plate
0022	Northern Calif-04	Gorda plate
0026	Northern Calif-05	Gorda plate
0035	Northern Calif-07	Gorda plate
0067	Trinidad	Gorda plate
0071	Taiwan SMART1(5)	Deep offshore event
0084	Trinidad offshore	Gorda plate
0086	Taiwan SMART1(25)	Deep offshore event
0093	Pelekanada, Greece	Deep event
0095	Taiwan SMART1(33)	Deep offshore event
0109	Taiwan SMART1(45)	Offshore event
0142	St Elias, Alaska	Subduction interface event
0153	Northwest China-01	Poorly known event
0154	Northwest China-02	Poorly known event of moderate depth
0155	Northwest China-03	Poorly known event of moderate depth
0156	Northwest China-04	Poorly known event of moderate depth

The remaining earthquakes are from a variety of active tectonic regions, as indicated in Table 2.3. Several investigators have shown that ground motion relationships based on California data are consistent with strong motion data in other active tectonic regions [Italy (Sabetta and Pugliese 1996); the Mediterranean basin (Ambraseys et al. 1996); Japan (Fukushima and Tanaka 1990)]. It has also been common to include ground motions from earthquakes such as Gazli, 1976, and Tabas, 1978, in developing ground motion models for application to California (Abrahamson and Silva 1997; Campbell 1997; Sadigh et al. 1997). We start with the hypothesis that the ground motions from these separate active tectonic regions are similar and examine this hypothesis during model development.

Recordings made in large buildings and at depth were removed¹, eliminating several additional earthquakes, notably the 1935 Helena, Montana, and several Imperial Valley, California, earthquakes recorded at the old Imperial Valley Irrigation District site. We kept records from sites that have been characterized as having topographic effects (e.g., Tarzana Cedar Hill nursery, Pacoima dam left abutment). Our rationale for including these records is that the effect of topography has not been systematically studied for all of the records in the database, and many other recording stations may have topographic enhancement or suppression of ground motions. Topographic effects are considered to be part of the variability introduced into ground motions by travel path and site effects.

The ground motion measure used in this model is the orientation-independent ground motion measure GMRotI50 defined by Boore et al. (2006). Use of this ground motion measure eliminates recordings for which only a single horizontal component was obtained, notably the Cholame-Shandon Array #2 recording from the 1966 Parkfield earthquake.

The ground motion model developed in this study explicitly accounts for site conditions. Therefore, recordings from sites for which there is no available information of the local soil conditions were excluded. These data were limited to a few recordings from earthquakes in Greece and Turkey.

¹ These recordings are identified as having “Geomatrix” C1 site code of C, D, E, G, and H (non-abutment sites).

Table 2.3 Regional distribution of selected recordings.¹

Active Region	# of Earthquakes	# of Recordings
Alaska	3	57
Armenia	1	1
California	81	1311
Canada	1	3
Georgia	1	5
Greece	8	13
Idaho	2	5
Iran	2	14

Italy	8	43
Japan	1	22
Netherlands	1	3
New Zealand	4	5
Nicaragua	2	2
Russia	1	1
San Salvador	1	2
Taiwan	6	1753
Turkey	7	56
Totals	131	3297

¹Numbers given in this table do not reflect the distance truncation at 70 km.

During the PEER-NGA project, an issue was raised concerning the use of data from aftershocks. We have included data from aftershocks but have allowed for the possibility that there may be systematic differences in the ground motion amplitudes produced by main shocks and aftershocks. Our reason for including the aftershock data is that they provide additional information to constrain the soil amplification model parameters.

As discussed later in the report, we limit the data to recordings within 70 km of the earthquake rupture in order to remove the effects of bias in the strong motion data sample. The combined limitations result in a total data set of 1950 recordings from 125 earthquakes. Figure 2.6 shows the distribution of the selected data in terms of magnitude, distance, and the average shear-wave velocity of the upper 30 m (V_{S30}). The earthquakes and recordings used in the regression analysis are tabulated in Appendix A.

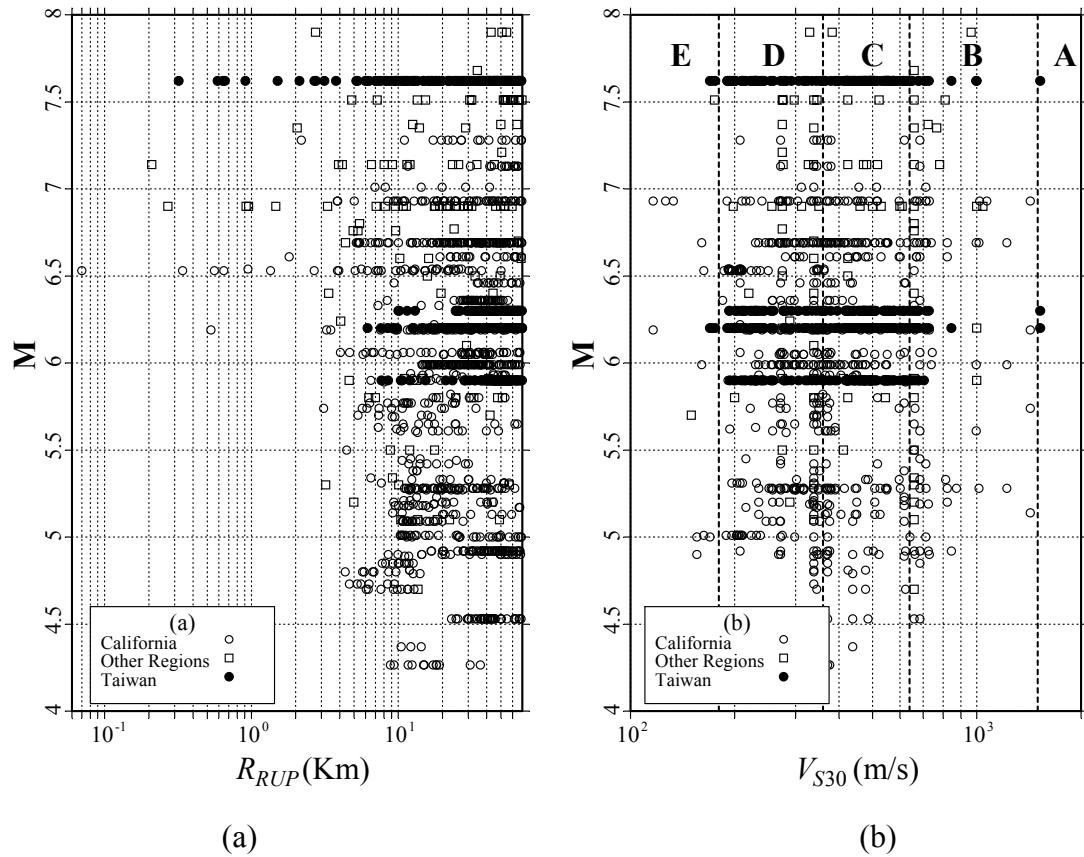

Fig. 2.6 (a) Magnitude-distance-region distribution of selected recordings. (b) V_{S30} -magnitude-region distribution of selected recordings. V_{S30} velocity ranges for NEHRP site classes indicated by vertical dashed lines.

Finally, in the regression of response spectra at a spectral period T , we included only recordings that have a minimum usable spectral frequency that is lower than $1/T$. This selection leads to a decreased data set size as the spectral period increases (Fig. 2.7).

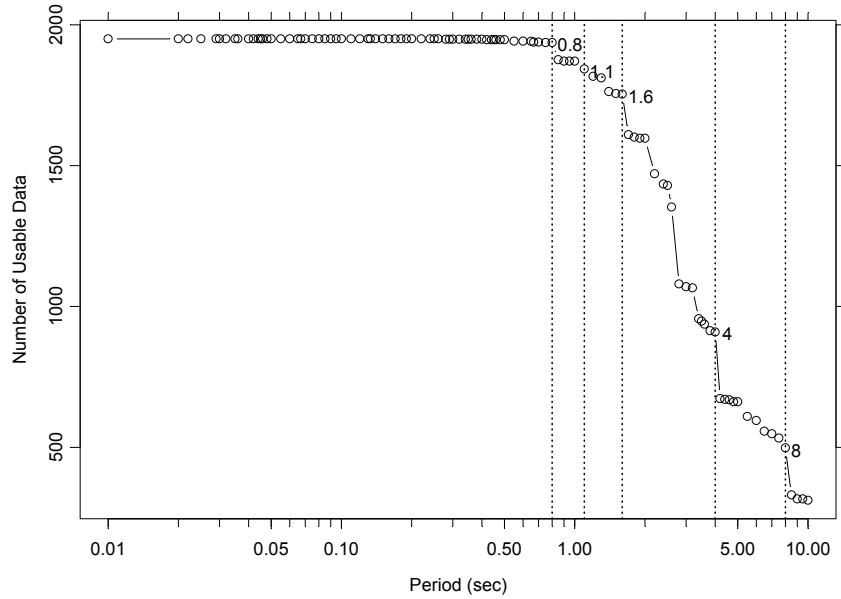

Fig. 2.7 Reduction of number of usable data as a function of spectral period.

2.3 SUPPLEMENTAL STRONG-MOTION DATA

The PEER-NGA strong motion data were supplemented with ground motion data from the California ShakeMap system. Acceleration time histories recorded at ShakeMap's high broadband stations, as well as USGS and CSMIP strong-motion stations, for the 2001 Anza, 2002 Yorba Linda, and 2003 Big Bear City earthquakes were provided by David Boore (written communication, USGS 2005). Peak acceleration values for many other events were supplied by Jack Boatwright and Linda Seekins (written communication, USGS 2005, 2006; see Appendix D) or obtained from the ShakeMap website. Estimates of site conditions at the ShakeMap stations were provided by Chris Wills based on surface geology (Wills and Clahan 2006) and by Jack Boatwright. The supplemental data were used to provide additional guidance on functional forms and provide additional constraints on coefficients of the ground motion model.

3 Model Formulation

Using algebraic expressions to represent the average behavior observed in the empirical strong-motion data, the empirical ground motion model developed here attempts to capture the effects of the amount of energy radiated by the earthquake source, the attenuation of seismic waves along the propagation path due to geometric spreading and energy absorption, and local modification of the seismic waves by the near-surface materials. The form of these expressions is guided by trends in the data, simple seismological models, past experience, and examination of the results of 1-D and 3-D ground motion simulations (Somerville et al. 2006; Day et al. 2008; Silva 2008; Walling 2008) conducted as part of the PEER-NGA project.

3.1 SEISMIC SOURCE SCALING

3.1.1 Effect of Earthquake Size

We use moment magnitude (\mathbf{M}) as the simplest measure for correlating the amount of energy radiated by an earthquake with the resulting amplitudes of ground motions. Many empirical ground motion models, including Sadigh et al. (1997), use a polynomial function for scaling the \ln of ground motions y with magnitude of the form:

$$\ln(y) \propto C_2(T) \times \mathbf{M} + C_3(T) \times (m_C - \mathbf{M})^n \quad (3.1)$$

where coefficients C_3 and possibly C_2 vary with spectral period T , the exponent n is typically in the range of 2–3, and coefficient m_C is independent of T . Figure 3.1(a) shows the magnitude scaling of pseudo-spectral acceleration, y , at a rupture distance of 30 km obtained from the Sadigh et al. (1997) ground motion model.

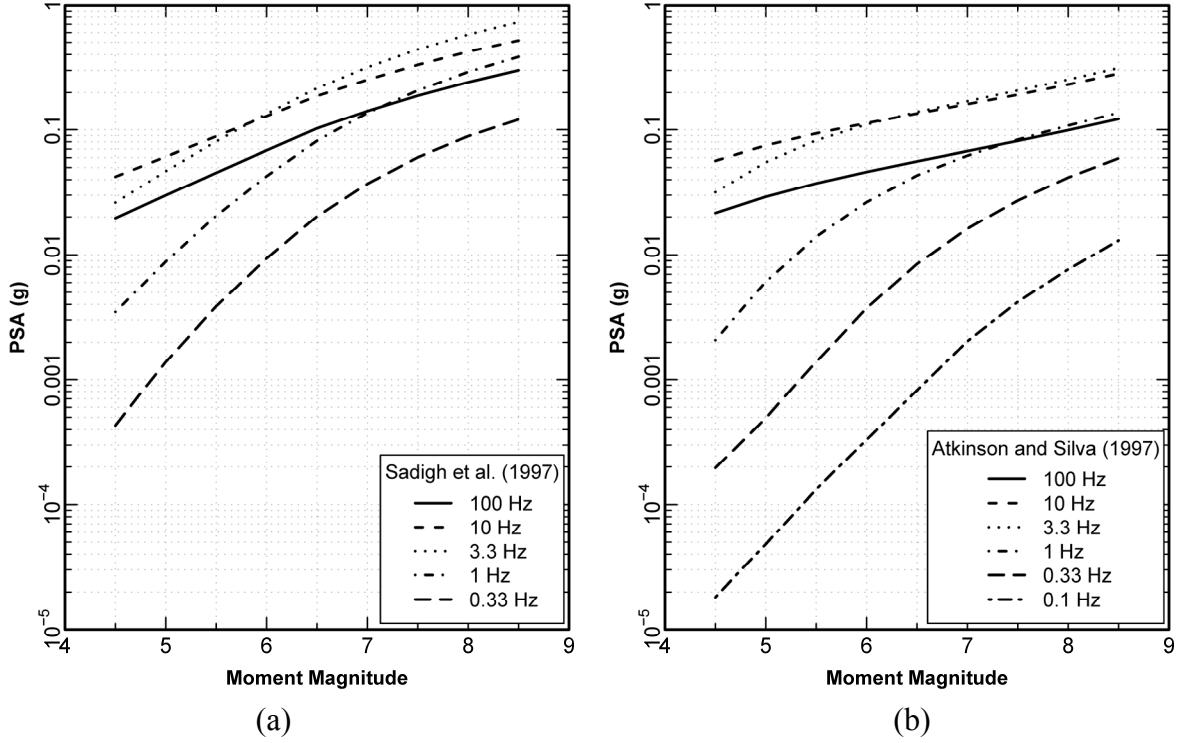

Fig. 3.1 Magnitude scaling of pseudo-spectral acceleration at distance of 30 km computed using (a) Sadigh et al. (1997) and (b) stochastic ground motion model, and Atkinson and Silva (1997) source model for California earthquakes.

In contrast, seismological models for earthquake source spectra suggest an alternative form for magnitude scaling. Figure 3.1(b) shows magnitude scaling relationships at a distance of 30 km, computed using the stochastic ground motion model (Boore 2003) and the Atkinson and Silva (1997) empirical source spectra model for California earthquakes. For spectral frequencies of 10 Hz and higher, the magnitude scaling of $\ln(y)$ is approximately linear at a relatively flat slope in the magnitude range of $5 \leq M \leq 8.5$, representing scaling of the source spectrum above the corner frequency. For frequencies of 0.33 Hz and lower, the magnitude scaling in the range of $5 \leq M \leq 7$ is again approximately linear, but at a much larger slope than for high-frequency motions, reflecting scaling of the source spectrum below the corner frequency. The transition between the two approximately linear scaling regions occurs over the magnitude range where the corner frequency of the source spectrum is near the spectral frequency of the ground motion. As the spectral frequency of the ground motions decreases, the magnitude range for this transition shifts to larger magnitudes, reflecting the decrease in corner frequency with increasing magnitude.

The shape of the magnitude scaling curves shown in Figure 3.1(b) is modeled by the expression:

$$\ln(y) \propto c_2 \mathbf{M} + \frac{1}{c_n} (c_2 - c_3) \times \ln[1 - \exp\{c_n(c_{\mathbf{M}} - \mathbf{M})\}] \quad (3.2)$$

Coefficient c_2 is the slope of the magnitude scaling relationship for earthquakes whose theoretical corner frequency is well above the spectral frequency of interest, and c_3 is the slope for earthquakes whose corner frequency is well below the spectral frequency. Coefficient c_n controls the width of the magnitude range over which the transition from c_2 scaling to c_3 scaling occurs. Coefficient $c_{\mathbf{M}}$ is the magnitude at the midpoint of this transition and its value varies with the spectral period of the ground motion parameter y . The function form of Equation (3.2) was tested by fitting a set of ground motion response spectra simulated using the program SMSIM (Boore 2005) and the Atkinson and Silva (2000) stochastic ground motion. Figure 3.2 shows the magnitude scaling obtained from the simulated ground motions. As indicated on the figure, the functional form of Equation (3.2) can provide a close fit to the simulations.

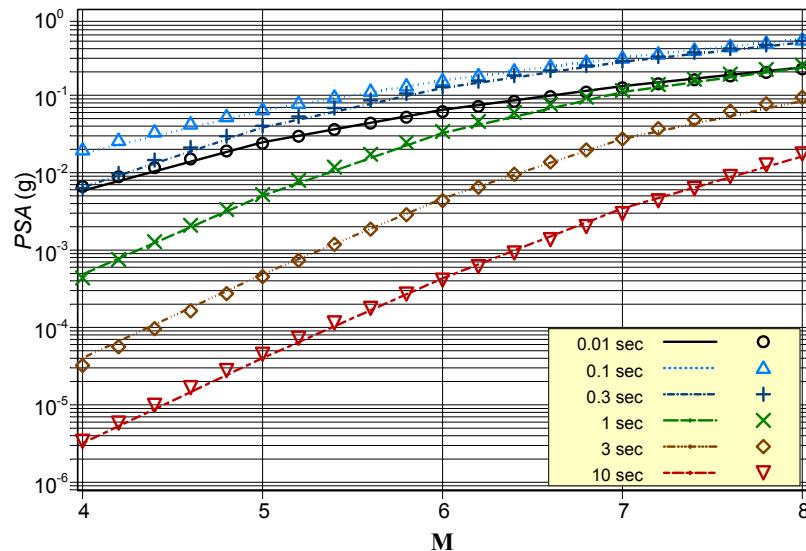

Fig. 3.2 Magnitude scaling predicted by seismic source model of Atkinson and Silva (2000) (points) and result of fitting Eq. (3.2) to predicted data (lines).

To evaluate the utility of Equations (3.1) and (3.2), we put together a set of peak acceleration data in the distance range of 30–50 km and the V_{S30} range of 300–400 m/s from the PEER-NGA database and from the ShakeMap data (Appendix D). These values, shown in Figure 3.3, were fit using three alternative scaling relationships. They are the quadratic form of Equation (3.1) with an exponent n of 2; the Sadigh et al. (1997) form of Equation (3.1) with an n equal to 2.5 and m_C equal to 8.5; and the magnitude scaling defined by Equation (3.2). The fit of the Sadigh et al. (1997) form of Equation (3.1) to the data on Figure 3.3 produced C_2 equal to 1.0. In fitting Equation (3.2) to the data on Figure 3.3, c_2 was constrained to be 1.06, the value obtained from the analysis of spectral accelerations simulated for California earthquakes (see discussions below). All three forms provide essentially equally good fits to the data. The empirical data are not sufficient to distinguish between magnitude-scaling defined by Equation (3.1) or (3.2). We prefer the scaling form of Equation (3.2) because we believe that it better represents our current concept of earthquake source spectra scaling with earthquake magnitude.

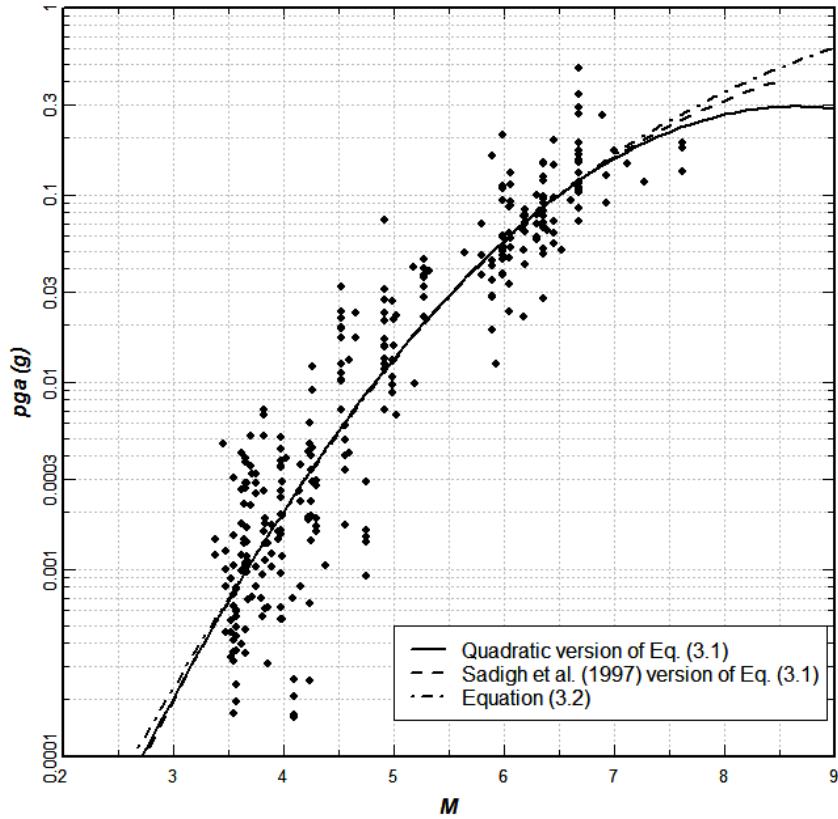

Fig. 3.3 Peak acceleration data from PEER-NGA database and from ShakeMap (Appendix D) for the distance range $30 \leq R_{RUP} \leq 50$ and the velocity range $300 \leq V_{S30} \leq 400$ fit by alternative function forms of magnitude scaling.

As explained earlier, in Equation (3.2) c_3 represents scaling of ground motion spectra below the corner frequency where the source spectra are directly proportional to seismic moment, M_0 . Because $\mathbf{M} \propto \sqrt[3]{M_0}$, theoretically, c_3 should equal $1.5 \times \ln(10)$ or 3.45 if the magnitude scaling of Fourier amplitude spectra can be directly carried over to the magnitude scaling of response spectra. We decided to fix c_3 at this value. Far-field simulations based on the updated source spectral model for California earthquakes defined by Atkinson and Silva (2000) produces scaling of $\ln(y) \propto 1.06\mathbf{M}$ for spectral period above the source corner frequency. In the Sadigh et al. (1997) form of Equation (3.1), coefficient C_2 also represents the magnitude scaling of the source spectra at distances large enough that the source can be considered a point. The Sadigh et al. (1997) values of C_2 were 1.0–1.1. Therefore, coefficient c_2 was fixed at 1.06. Coefficients c_n and $c_{\mathbf{M}}$ were obtained by fitting the strong motion data.

3.1.2 Style of Faulting Effects

Our exploratory analysis of the NGA data indicated that reverse-faulting earthquakes produce larger high-frequency motions than strike-slip earthquakes. This effect diminishes as the spectral period increases, with the motion from strike-slip earthquakes becoming the larger of the two at long periods, similar to findings by other investigators (Abrahamson and Silva 1997; Campbell and Bozorgnia 2003; Ambraseys et al. 2005). Chiou et al. (2000) showed that when the geometric hanging-wall effect was accounted for by using the R_{RMS} distance measure, reverse-faulting earthquakes still produced statistically significant higher motions than strike-slip earthquakes.

Some empirical models have shown that normal-faulting/extensional regime earthquakes produce lower ground motions than strike-slip earthquakes (Spudich et al. 1999; Ambraseys et al. 2005) while others have included normal faulting and strike slip together in a single class (Abrahamson and Silva 1997; Sadigh et al. 1997; Campbell and Bozorgnia 2003). In our exploratory analysis of NGA data, the style of faulting effect for normal faults was found to be statistically significant (p -values slightly less than 0.05) only when normal faulting was restricted to rake angles, λ , in the range of -120° to -60° ; with normal-oblique earthquakes included in the same style-of-faulting class as strike-slip earthquakes.

3.1.3 Other Source Effects

Other source parameters examined include source depth and the difference between aftershocks and main shocks. In the preliminary analyses it was found that the NGA data exhibited a statistically significant dependence on source depth parameterized as the depth to top of rupture, Z_{TOR} . Figure 3.4 shows inter-event residuals for models fit to the pga data without and with Z_{TOR} scaling. The inter-event residuals for the fit without Z_{TOR} scaling show a clear trend, while those for the fit with Z_{TOR} scaling do not. Figure 3.4(c) shows the percent reduction in inter-event standard error achieved by including Z_{TOR} scaling.

As indicated earlier in Section 2.2, we include aftershocks in our analyses to provide additional data to help constrain the coefficients of the site response model. We found that aftershocks tend to produce lower motions than main shocks with similar magnitudes. Hence we included this difference in the ground motion model. We also found that the style of faulting effects were much weaker for aftershocks than for main shocks. Furthermore, aftershocks showed a stronger dependence on Z_{TOR} than main shocks. Therefore, the ground motion model incorporates separate depth-dependence for main shocks and aftershocks, and no style of faulting effects for aftershocks.

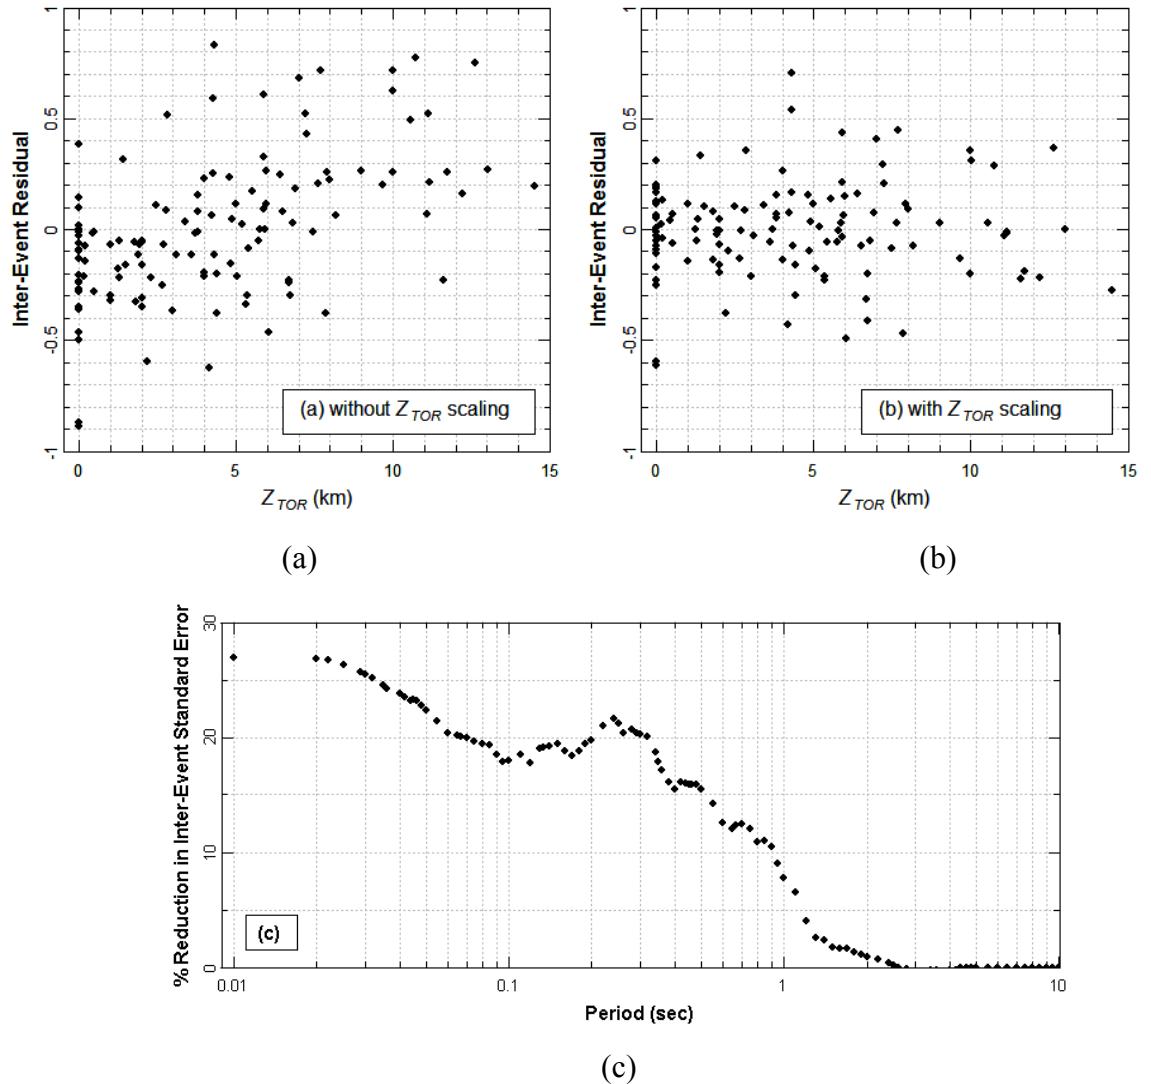

Fig. 3.4 Effect of source depth on inter-event residuals: (a) pga data fit without Z_{TOR} scaling, (b) pga data fit with Z_{TOR} scaling, (c) reduction in inter-event standard error resulting from including Z_{TOR} scaling.

3.2 DISTANCE SCALING

The scaling or attenuation of ground motion amplitude with distance from the earthquake rupture involves two primary effects, geometric spreading and energy absorption along the travel path due to material damping and wave scattering. In most empirical ground motion models these effects are modeled by the functional form:

$$\ln(y) \propto C_{Geometric} \times \ln\left[\left(R^n + C_{Source_Size}^n\right)^{\frac{1}{n}}\right] + \gamma \times R \quad (3.3)$$

where $C_{Geometric}$ nominally defines the rate of attenuation due to geometric spreading, γ defines the rate of anelastic attenuation, typically quantified in terms of the quality factor Q . Coefficient C_{Source_Size} accounts for the effect of the source size on geometric spreading. Coefficient $C_{Geometric}$ interacts with C_{Source_Size} and n to define distance scaling at small distances from the source and interacts with γ to define distance scaling at large distances from the source. These two interactions are examined below.

3.2.1 Near-Source Distance Scaling

Of foremost interest to engineering application in active tectonic regions is the effect of extended source dimensions that leads to magnitude-dependent attenuation rates within the distance range of 0–50 km or more. The consequence of this effect is what has been termed near-source saturation—less magnitude scaling at small source-site distances than at large source-site distances. Two approaches have been used to model this effect within the framework defined by Equation (3.3). One approach uses a magnitude-independent value of $C_{Geometric}$ combined with a magnitude-dependent value for C_{Source_Size} [Sadigh et al. (1997) with exponent $n = 1$; Campbell (1993) and Campbell and Bozorgnia (2003) with $n = 2$]. The alternative approach has been to use a magnitude-dependent value for $C_{Geometric}$ combined with a magnitude-independent value for C_{Source_Size} [(Idriss 1991, written communication 2002) with $n = 1$; (Abrahamson and Silva 1997) with $n = 2$]. Figure 3.5 illustrates the behavior of these approaches to distance scaling as implemented in recent ground motion models. The attenuation behavior of the four models shown in Figure 3.5 can be illustrated by plotting the attenuation rate, defined as $\partial \ln(y) / \partial \ln(R)$, versus distance. Figure 3.6 shows the results. The effect of the value of the exponent n is seen by comparing the models shown on the left for exponent $n = 1$ to those shown on the right with $n = 2$. Use of $n = 2$ results in the rate of attenuation approaching the value defined by $C_{Geometric}$ at relatively short distances, allowing an interpretation of its value as a direct estimate of the rate of geometric spreading. Use of $n = 1$ results in the attenuation rate approaching the value of $C_{Geometric}$ slowly and its value cannot be directly equated with the rate of geometric spreading at distances less than 50 km. Figure 3.7 shows the magnitude scaling, defined as $\partial \ln(y) / \partial M$, for the four ground motion models shown in Figure 3.5. The steps in the values of $\partial \ln(y) / \partial M$ occur where there are changes in the model parameters for different magnitude ranges. The different implementations of Equation (3.3) also produce differences in

ground motion scaling with magnitude at large distances from the source. The models that use a magnitude-independent $C_{Geometric}$ (top row of Fig. 3.7) approach distance-independent magnitude scaling at large distances, while those that use magnitude-dependent $C_{Geometric}$ produce distant-dependent magnitude scaling at all distances.

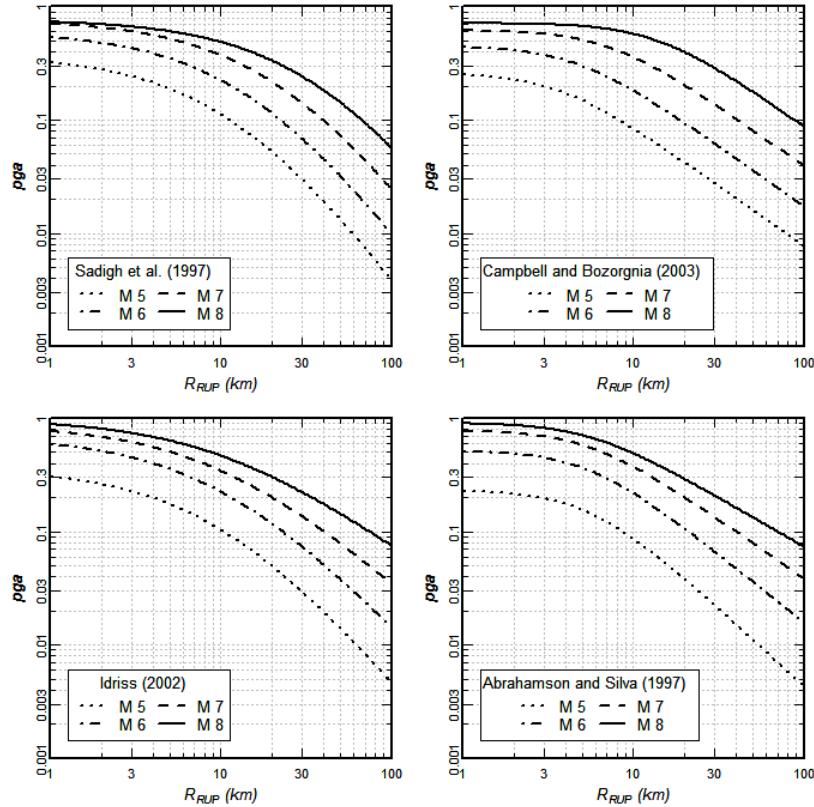

Fig. 3.5 Illustration of functional forms used to capture magnitude-dependence of distance attenuation for distances less than 100 km. All plots are for rupture distance to a vertical strike-slip fault rupturing the surface. Values for Campbell and Bozorgnia (2003) were computed using a minimum R_{SEIS} of 3 km.

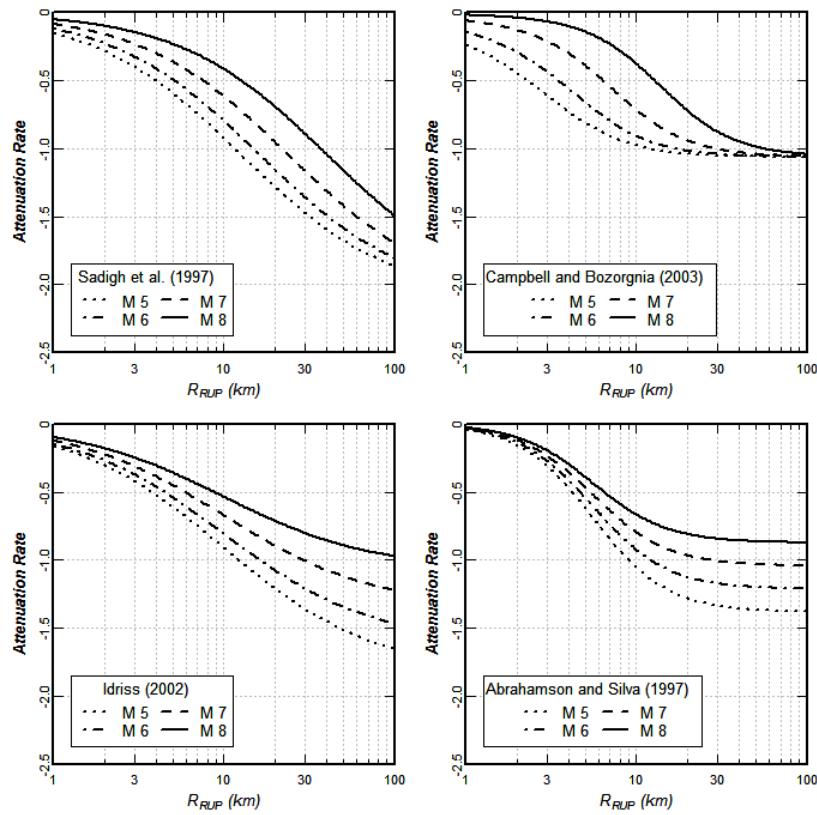

Fig. 3.6 Plots of the instantaneous slope of attenuation curve for the four ground motion models shown in Fig. 3.5. Attenuation rate defined as $\partial \ln(pga) / \partial \ln(R)$.

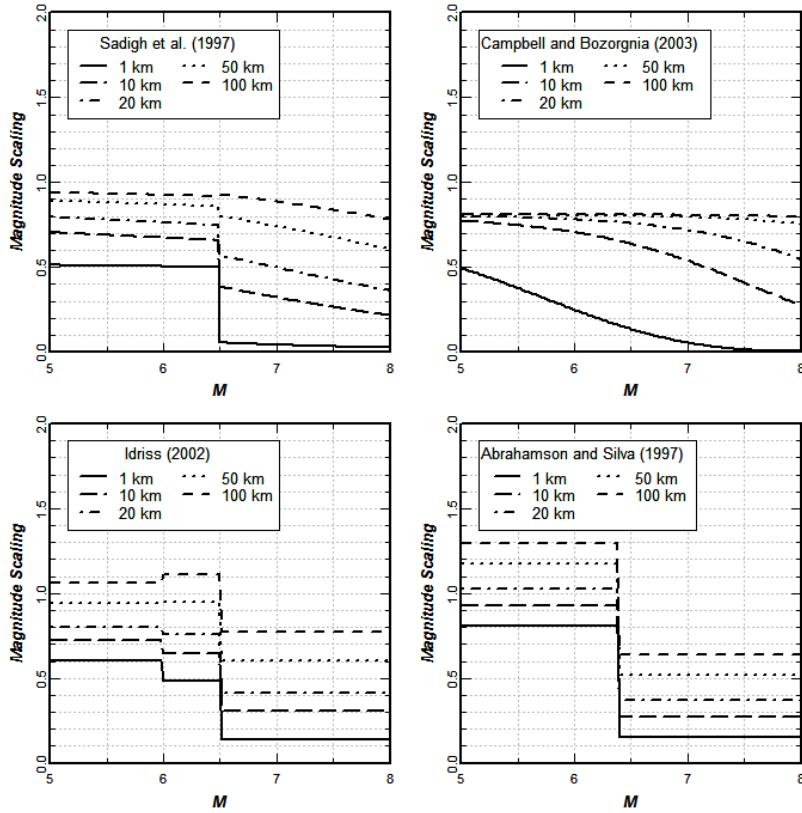

Fig. 3.7 Plots of magnitude scaling at a range of distances produced by form of the attenuation curve for the four ground motion models shown in Fig. 3.5. Magnitude scaling is defined as $\partial \ln(pga) / \partial M$.

Based on our examination of the alternative forms of Equation (3.3) we conclude that they all provide reasonable fits to the empirical data. Discrimination among them would require a great deal more data at distances less than 10 km. The data show magnitude-dependence in the rate of attenuation at all distances. However, we believe that the mechanisms that cause this behavior may be different at different distances. At distances less than ~ 50 km, magnitude-dependence is due to the effect of extended sources. This effect can be modeled by all of the functional forms shown in Figure 3.5. However, at large distances, > 100 km, we think that another effect may be causing magnitude-dependence in the attenuation of response spectral ordinates—the interaction of path Q with the differences in source Fourier spectra as a function of magnitude. This concept is explored below. We prefer to use a model form that allows for separation of the effect of magnitude scaling at small and large distances, and therefore select the magnitude-independent form of $C_{Geometric}$. This form allows the use of Equation (3.2) to define magnitude scaling at large distances from the source.

We examined the alternatives for the exponent n . As shown by the upper right-hand plot in Figures 3.5 and 3.6, use of $n = 2$ allows the model to approach a constant geometric spreading rate at distances greater than about $2 \times C_{\text{Source_Size}}$. After experimenting extensively with this form, we concluded that $n = 2$ resulted in too little distance scaling over the distance range of 0–10 km for large-magnitude earthquakes, and we use exponent $n = 1$, resulting in the form used by Sadigh et al. (1997). Instead of the piece-wise linear model for $C_{\text{Source_Size}}$ used by Sadigh et al (1997), we use a smooth function for the magnitude scaling of $C_{\text{Source_Size}}$ over the full magnitude range, accomplished by using the relationship:

$$C_{\text{Source_Size}}(\mathbf{M}) = c_5 \cosh\{c_6 \max(\mathbf{M} - 3, 0)\} \quad (3.4)$$

The use of Equation (3.4) has the property that $C_{\text{Source_Size}}$ varies smoothly from a constant ($C_{\text{Source_Size}} = c_5$) at small magnitudes ($\mathbf{M} \leq 3$) to $C_{\text{Source_Size}} \propto \exp(c_6 \mathbf{M})$ at large magnitudes.

3.2.2 Distance Scaling at Large Distances

Many studies of the attenuation of ground motion Fourier amplitudes with distance have indicated that there is a change in the rate of geometric spreading from approximately proportional to $1/R$ at short distances to $1/\sqrt{R}$ at large distances, with this transition occurring in the range of 40–70 km. This change has been interpreted to be the combination of the effects of post-critical reflections from the lower crust and transition from direct body wave to Lg wave spreading (Atkinson and Mereu 1992). Models of the decay of Fourier spectra with distance in California have found or assumed that the geometric spreading is proportional to $1/\sqrt{R}$ for distances greater than 40 km (Raoof et al. 1999; Erickson et al. 2004) and this form of geometric spreading was used by Atkinson and Silva (2000) to model strong ground motions. Earlier, Atkinson and Silva (1997) used a trilinear form of attenuation similar to that defined by Atkinson and Mereu (1992), but indicated that a bilinear form would also work as well.

We explored this effect by modeling spectral accelerations from 666 broadband recordings from three small Southern California earthquakes (2001 Anza, \mathbf{M} 4.92; 2002 Yorba Linda, \mathbf{M} 4.27; and 2003 Big Bear City, \mathbf{M} 4.92; NGA events 0163, 0167, and 0170,

respectively). These data were fit with three functional forms, a model with a single value of $C_{Geometric}$ at all distances (one-slope model):

$$\begin{aligned}\ln(y) &= C_1 + C_2 F_{BBC} + C_3 F_{YL} + C_4 \ln(R_0) + \gamma R + \phi_1 \ln(V_{S30} / 400) \\ R_0 &= \sqrt{R^2 + 6^2}\end{aligned}\quad (3.5a)$$

a model in which $C_{Geometric}$ at large distances becomes one half the value at small distances (two-slope model):

$$\begin{aligned}\ln(y) &= C_1 + C_2 F_{BBC} + C_3 F_{YL} + C_4 \{\ln(R_1) + \ln(R_2) / 2\} + \gamma R + \phi_1 \ln(V_{S30} / 400) \\ R_0 &= \sqrt{R^2 + 6^2}, R_1 = \min(R_0, C_8), R_2 = \max(1, R_0 / C_8)\end{aligned}\quad (3.5b)$$

and a model in which $C_{Geometric}$ is fixed at -0.5 for larger distances (two-slope, second fixed model):

$$\begin{aligned}\ln(y) &= C_1 + C_2 F_{BBC} + C_3 F_{YL} + C_4 \ln(R_1) - 0.5 \ln(R_2) + \gamma R + \phi_1 \ln(V_{S30} / 400) \\ R_0 &= \sqrt{R^2 + 6^2}, R_1 = \min(R_0, C_8), R_2 = \max(1, R_0 / C_8)\end{aligned}\quad (3.5c)$$

Dummy variables F_{BBC} and F_{YL} along with C_1 were used as earthquake terms; we did not use magnitude scaling with random effect terms because the magnitude range is small (4.33–4.92). The analysis was conducted for spectral periods in the range of 0.01–5 sec. Examination of the recordings indicated that they could be used without processing to periods at least as long as 5 sec.

Figure 3.8 shows the results of fitting the above three equations to the data. At all spectral periods, the two-slope models produced slightly smaller standard errors than the single slope model. The location for the break in slope varied between 40 and 60 km distance. In addition, use of the single-slope model produces unrealistic positive values of the anelastic attenuation term γ for longer period motions, a fact also noted by Atkinson and Silva (1997).

Examination of ShakeMap pga data from many of the better-recorded small-magnitude earthquakes shows that there is a decrease in the rate of attenuation at distances in the range of 40–70 km (Appendix D). Tests of the PEER-NGA data also show that a two-slope model is statistically significant with a slope break also in the range of 45–60 km. Examination of the 1-D

rock numerical simulation data (Somerville et al. 2006) also indicate that a two-slope model provides a good fit with a break in slope at about 60 km.

Based on the above observations, we adopted the concept of a change in the rate of attenuation occurring at some transition distance. If one were to use an abrupt change in rate of attenuation, then the best-fit change-point distance may vary from earthquake to earthquake as a function of a number of parameters including source depth, source size, and the local crustal thickness. Instead, we use a smooth transition over a broad distance range to provide a fit to the average behavior of all earthquakes represented in the selected database.

3.2.3 Formulation for Distance Attenuation

Equation (3.5d) defines the formulation used in our study for distance attenuation. It incorporates magnitude-dependent extended source effects, potentially magnitude-dependent wave propagation effects on response spectra at large distances, and a smooth transition from dominance of ground motions by direct waves at small distances, modeled by attenuation coefficient c_4 , to dominance by Lg waves at large distances, modeled by attenuation coefficient c_{4a} .

$$\ln(y) \propto c_4 \ln[R_{RUP} + c_5 \cosh\{c_6 \max(\mathbf{M} - 3, 0)\}] + (c_{4a} - c_4) \ln \sqrt{R_{RUP}^2 + c_{RB}^2} + \gamma(\mathbf{M}) R_{RUP} \quad (3.5d)$$

Coefficient c_4 was examined by analyses of PEER-NGA data and ShakeMap data. It was concluded that a range of values for c_4 would provide satisfactory fits to the data with adjustments to the rate of near-source attenuation occurring through changes of coefficients c_5 and c_6 . Therefore, c_4 was fixed at -2.1, the value obtained originally by Sadigh et al. (1997) for rock sites.

Coefficient c_{RB} defines the midpoint of the transition in rate of attenuation from c_4 to c_{4a} . As discussed above similar transition points were found from analyses of the extended data sets for the three small southern California earthquakes, the NGA data, and the 1-D rock simulations. We therefore, set the value of c_{RB} to be 50 km, the central value of the estimates we obtained from the various data sets.

The appropriate value of the attenuation rate at distances beyond c_{RB} , coefficient c_{4a} , cannot be readily determined from the data because it is highly correlated with the assessment of the anelastic attenuation coefficient γ , as had been noted by many previous investigators (Atkinson 1989; Frankel et al. 1990). Therefore, we assume that c_{4a} equals to -0.5, and let the anelastic attenuation coefficient γ account for departures from this value.

The anelastic attenuation coefficient γ is allowed to be magnitude dependent. Boatwright et al. (2003) found magnitude-dependence in the anelastic attenuation coefficient from their study of pga and pgv from northern California ShakeMap, with increasing magnitude producing smaller absolute values of γ (less energy absorption). In addition, stochastic simulations of ground motions using a magnitude-independent Q model produce magnitude-dependence in the resulting anelastic attenuation coefficient γ obtained from fits to response spectral ordinates (Campbell 2003). This effect was also noted in our fitting of ground motions simulated using the Atkinson and Silva (2000) ground motion model. The effect is likely due to a shift to lower-frequency ground motion driving the response of a damped oscillator (and driving pga , Boatwright et al. 2003) as the size of the earthquake increases. Estimation of $\gamma(M)$ is further discussed in the next section.

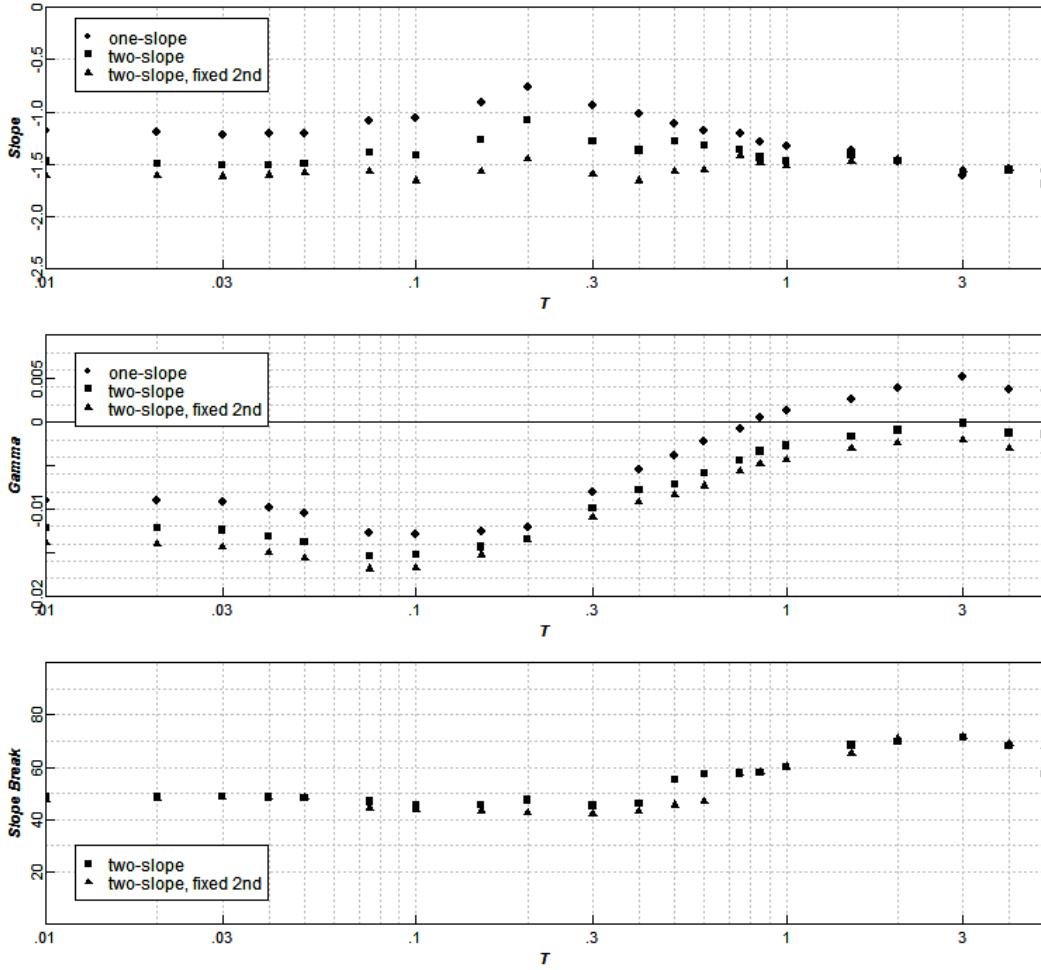

Fig. 3.8 Coefficients resulting from fits of Eqs. (3.5a), (3.5b), and (3.5c) to the broadband data for earthquakes 0163, 0167, and 0170. T is spectral period in sec.

3.2.4 Data Truncation and Estimate of γ

The initial analyses of the PEER-NGA data suggested that the anelastic attenuation coefficient γ in Equation (3.5d) was 50% larger in absolute value for earthquakes in Taiwan than for earthquakes in California or the other active tectonic regions represented in the selected database. This would imply that Q for Taiwan was significantly lower than Q for California or the other regions. However, review of the literature failed to produce studies that confirmed this result. In addition, the estimates of γ obtained from the extensive broadband data for the three southern California earthquakes were inconsistent with the values obtained for California earthquakes from fitting the PEER-NGA data.

These results led us to consideration of the effects of missing response data on the estimation of ground motion model coefficients. There are two forms of missing response data treated in the literature: censoring and truncation. Censoring occurs when a known set of instruments is triggered, but the response is only known to be below $y_{truncation}$. In this case, the number of censored observations and predictor variables for these observations (e.g., \mathbf{M} , R_{RUP} , and V_{S30}) are known for the censored sample. Truncation occurs when the observed sample is truncated at some response level $y_{truncation}$ such that no responses are reported below this level. The number of missing values and values of the predictor variables for these observations are unknown. The two forms of missing response variables lead to different forms of the sample likelihood function in fitting models by maximum likelihood.

Censoring/truncation of the strong motion database occur due to the occurrence of ground motions below the trigger threshold for the recording instruments and from the selective processing of recordings favoring those with larger amplitudes. Censoring/truncation occurs also from record processing as frequency bands with low signal/noise ratios are filtered out of the processed records. Although the number of possible recordings in a given earthquake is knowable, some instruments may have malfunctioned and there is not a complete accounting of the possible instruments available. Therefore, the truncation model is considered the more appropriate condition for the PEER-NGA database.

Evidence of truncation of the PEER-NGA data is shown in Figure 3.9. The solid data points are pga values for the processed acceleration time histories in the PEER-NGA database. The open data points are additional pga values obtained from other recordings. The PEER-NGA data and the extended data for each earthquake were fit using a truncated regression model (Toro 1981; Bragato 2004), and the truncation levels are shown by the dotted and dash-dotted lines, respectively, in Figure 3.9. For the Northridge earthquake, similar estimates of γ were obtained from the PEER-NGA and the extended data set. However, for the other three earthquakes, the estimate of γ obtained from the PEER-NGA data set were approximately 2/3 of the values obtained from the extended data sets, indicating that truncated regression using the PEER-NGA data set tends to underestimate the appropriate absolute value of γ .

To further investigate the underestimation of γ , extended pga and pgv data sets were developed for 11 earthquakes in the PEER-NGA database plus three additional recent California earthquakes (Table 3.1). The PEER-NGA set of earthquakes was supplemented by data from the Feb 2, 2000, Loma Linda; Dec 23, 2003, San Simeon; and the Sept 28, 2004, Parkfield

earthquakes. In addition, an extended data set was developed for the 1995 Kobe earthquake using the data presented in Fukushima et al. (2000). Additional pga data for Northridge (EQID 0127) were supplied by Vladimir Graizer (personal communication 2006). The remaining California data were obtained from the ShakeMap web pages, of which only the high broadband data were used. For each of these earthquakes, estimates of γ were made using truncated regression and using Equation (3.5d) to model distance attenuation with coefficient c_{4a} fixed at -0.5. To remove the influence of hanging-wall effects, hanging-wall and footwall sites were removed. As indicated by the results in Table 3.1, the absolute values of γ computed using only PEER-NGA data were typically smaller than those obtained from the extended data. The few cases where the PEER-NGA data produced larger (and often unrealistic) values of γ are for earthquakes with very limited samples in the PEER-NGA database (e.g., San Juan Bautista, Mohawk Valley).

Based on the above analyses we conclude that regression analyses using the PEER-NGA data will tend to underestimate the rate of anelastic attenuation due to data truncation and that the problem cannot be solved using truncated regression. Our solution is to estimate the anelastic attenuation coefficient γ from the extended data sets developed for individual earthquakes. We then estimate the remaining model coefficients from the PEER-NGA data truncated at a maximum distance of 70 km. This distance was selected by visual inspection as the point where, on average, data truncation may begin to affect the distribution of recordings in the PEER-NGA database. We believe that this (short-term) solution should provide an appropriate model for California earthquake ground motions. We also believe that the model properly represents the attenuation of ground motion at larger distances in California. The issue we have raised points out the need to systematically collect and process all recordings from moderate to large earthquakes in order to correctly model the attenuation of ground motions at large distances.

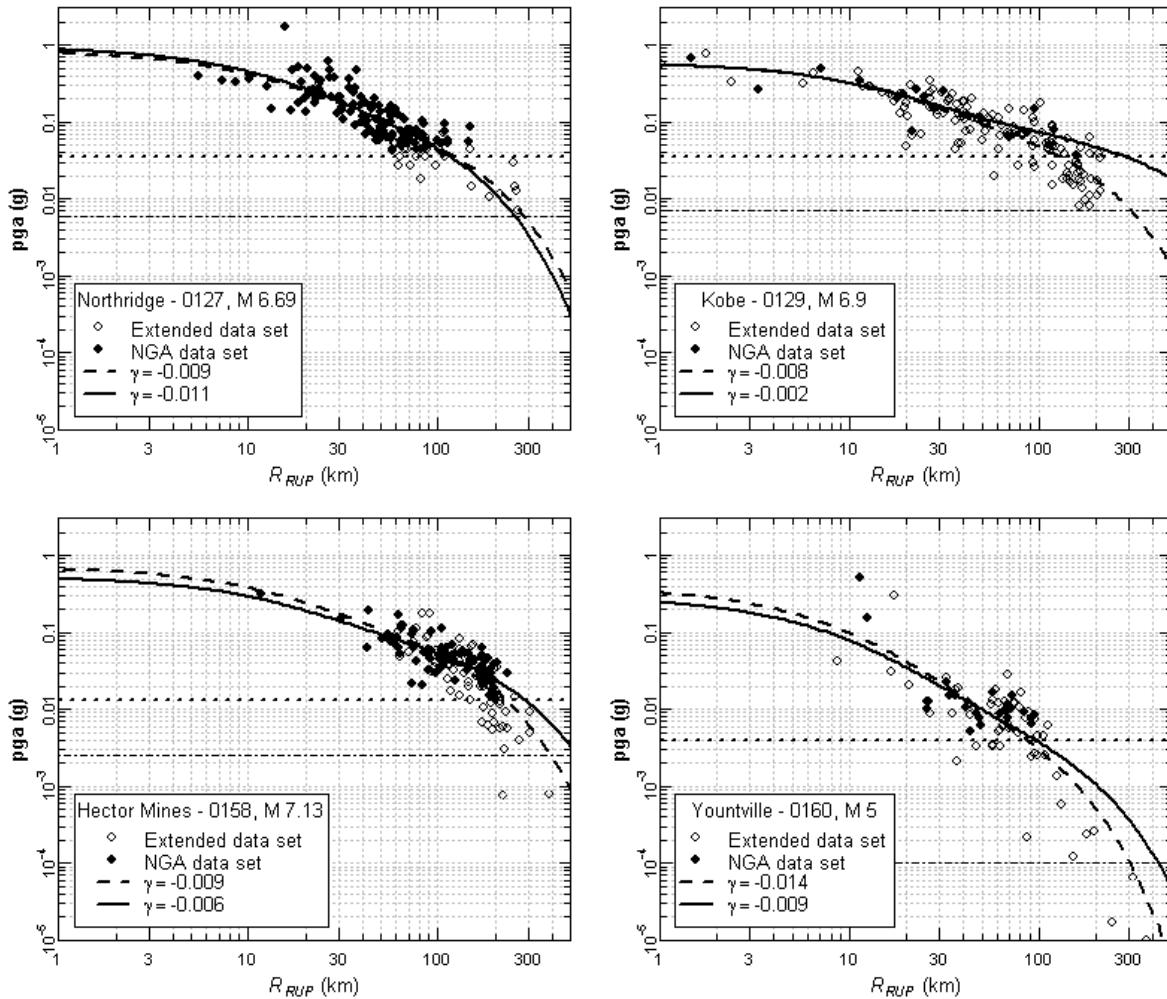

Fig. 3.9 Comparison of fits to expanded data sets (open plus solid points, dashed curve) and PEER-NGA data only (solid points, solid curve) for individual earthquakes using truncated regression. Truncation levels are indicated by the horizontal dashed lines for enhanced (dash-dotted) and PEER-NGA only (dotted) data sets. Hanging-wall sites were not included in fits for Northridge.

3.2.5 Magnitude Dependence of γ

The values of γ obtained from the extended data sets (shown in Fig. 3.10) show that γ decreases in absolute value with increasing magnitude, similar to results reported by others from analysis of empirical data (Campbell 1993) and stochastic ground motion simulations (Campbell 2003).

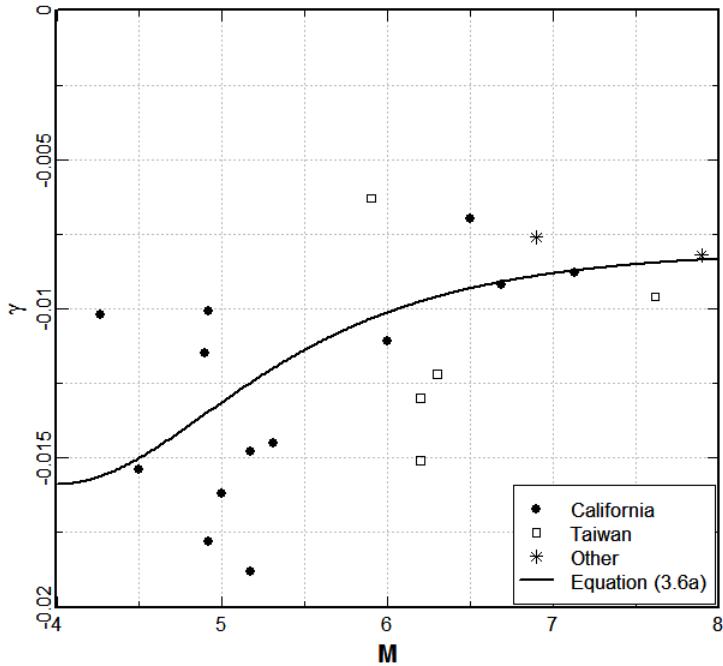

Fig. 3.10 Estimates of γ for individual earthquakes and model fit to California earthquake data.

Because we are interested primarily in modeling earthquake ground motions in the western United States, we develop a model for γ from the results for the 13 California earthquakes for which we developed extended data sets. The resulting relationship is:

$$\gamma(pga)_{\text{California}} = -0.00804 - 0.00785 / \cosh\{\max(M - 4, 0)\} \quad (3.6a)$$

This relationship is plotted in Figure 3.10. The limited data for earthquakes from other regions (Kobe, Japan; Denali, Alaska; Chi-Chi main shock and aftershocks, Taiwan) are generally consistent with this relationship. The data indicate that the value of γ for Taiwan may be slightly greater than that for California, but the difference is much less than the 50-percent larger values for Taiwan obtained from the initial regressions using the full PEER-NGA database. Equation (3.6a) provides a relationship for γ at pga . The relationships for other spectral periods were constructed by scaling the period-dependent γ estimated from the broadband data for the three small southern California earthquakes ($\gamma(T)_{\text{Anza-YL-BBC}}$) by the relative difference in γ at pga , that is:

$$\gamma(T)_{California} = \gamma(T)_{Anza-YL-BBC} \times \frac{\gamma(pga)_{California}}{\gamma(pga)_{Anza-YL-BBC}} \quad (3.6b)$$

Figure 3.11 compares the model developed for γ with values obtained from direct regression of the PEER-NGA data without imposing any distance truncation and without using truncated regression. The variation of γ with spectral period T is similar.

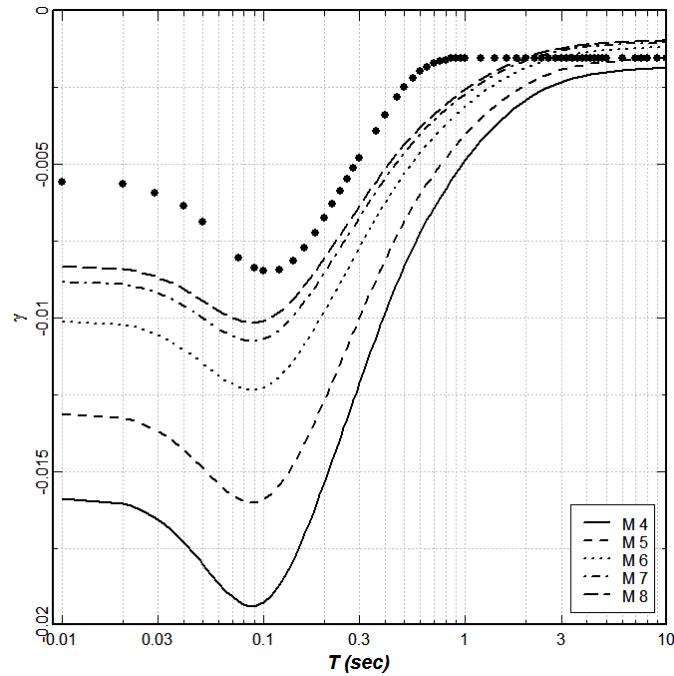

Fig. 3.11 Comparison of the model developed for γ (Eqs. 3.6a–b) versus values of γ obtained from regression without truncation (solid circles) of PEER-NGA data set.

3.3 HANGING-WALL EFFECTS

Based on analyses of ground motions from reverse earthquakes, Somerville and Abrahamson (1995) and Abrahamson and Somerville (1996) proposed the so-called hanging-wall effect in which ground motions are enhanced in the hanging wall of reverse earthquakes. The effect was attributed to the inability of the R_{RUP} distance measure to capture the general proximity of a hanging-wall site to rupture on the fault plane dipping beneath it. Chiou et al. (2000) performed extensive analyses of empirical and numerical modeling data for reverse fault ruptures and reached the same conclusion. They were able to remove the hanging-wall effect by using a root-

mean-squared distance measure, R_{RMS} . The hanging-wall effect is also seen in the 1-D rock ground motion simulations conducted for the PEER-NGA project (Somerville et al. 2006).

Table 3.1 Estimate of anelastic attenuation parameter γ for individual earthquakes.

EQID	Earthquake	M	PEER-NGA Data Set		Expanded Data Set		Region
			γ	Number of Recordings	γ	Number of Recordings	
0127	Northridge	6.69	-0.0108	122	-0.0092	154	California
0129	Kobe	6.9	-0.0020	22	-0.0076	157	Japan

	San Simeon	6.5			-0.0070	225	California

Abrahamson and Silva (1997) included the hanging-wall effect in their empirical ground motion model as a distance-dependent term with an abrupt switch from no effect to full effect as one crosses into the hanging-wall region. Boore et al. (1997) conclude that their use of R_{JB} implicitly accounts for the hanging-wall effect in that all sites directly above the rupture have $R_{JB} = 0$. Campbell and Bozorgnia (2003) introduces a smooth variation in the hanging-wall effect by tapering the effect from a maximum at $R_{JB} = 0$ to zero for $R_{JB} > 5$ km. We use the following model to represent the hanging-wall effect:

$$f_{HW} = F_{HW} \times \tanh\left(\frac{R_X \cos^2 \delta}{c_{9a}}\right) \times \left[1 - \frac{\sqrt{R_{JB}^2 + Z_{TOR}^2}}{R_{RUP} + 0.001}\right] \quad (3.7)$$

where δ is fault dip and R_X represents the site coordinate (in km) measured perpendicular to the fault strike from the surface projection of the up-dip edge of the fault plane, as illustrated in Figure 3.12. Note that R_X is negative for sites on the footwall side of the fault trace. Parameter F_{HW} is 1 for $R_X \geq 0$ and 0 for $R_X < 0$. Generalization of R_X 's definition to the case of a multi-segment fault can be found in Spudich and Chiou (2008).

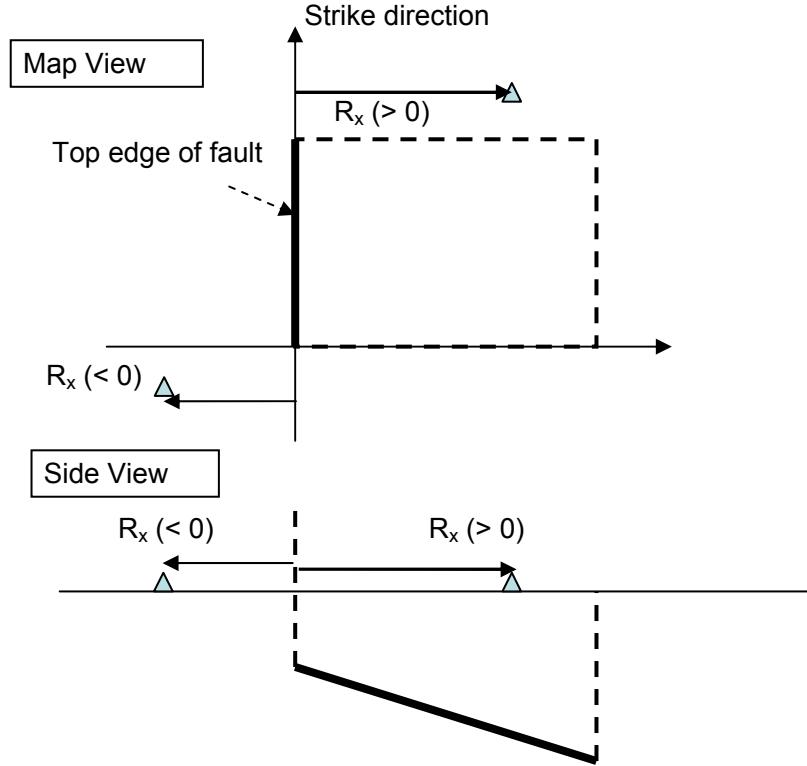

Fig. 3.12 Definition of variable R_X .

The motivation for Equation (3.7) is as follows. The third term of Equation (3.7) is motivated by the modeling of Boore et al. (1997) and Campbell and Bozorgnia (2003) in that f_{HW} decreases as R_{JB} increases. Placing R_{RUP} in the denominator produces a smooth transition in the spatial extent of the hanging-wall effect at various locations in the hanging wall. This behavior is demonstrated by the examples shown in Figures 3.13–3.14. Figure 3.13 shows a map view of a fault rupture with the top of rupture located at $x=0$ and the fault dipping toward positive x . Figure 3.14 shows the variation of $[1 - R_{JB} / R_{RUP}]$ with location along three lines for the case of $Z_{TOR} = 0$ (i.e., the top of rupture is at the ground surface). Line 1 runs from negative x values in the footwall to positive x values in the hanging wall. Lines 2 and 3 show the variation of

$[1 - R_{JB} / R_{RUP}]$ as one moves away from the rupture along strike. For hanging-wall sites not directly above but near the top of the rupture (Line 2) R_{RUP} is only slightly larger than R_{JB} and $[1 - R_{JB} / R_{RUP}]$ decreases rapidly as one move away from the rupture. For sites near the bottom edge of the rupture (Line 3) $R_{RUP} \gg R_{JB}$ and $[1 - R_{JB} / R_{RUP}]$ decreases more slowly as one moves away from the rupture. The function $[1 - R_{JB} / R_{RUP}]$ decays much more rapidly for Line 2 than for Line 3. Most of Line 2 lies outside of the hanging-wall region defined by Abrahamson and Somerville (1996) as subject to the hanging-wall effect, while much of Line 3 for small values of y lies near the hanging-wall region. The functional form $[1 - R_{JB} / R_{RUP}]$ gives similar spatial extent of the hanging-wall region to that defined by Abrahamson and Somerville (1996), but provides for a smooth transition in the level of the hanging-wall effect along the strike region.

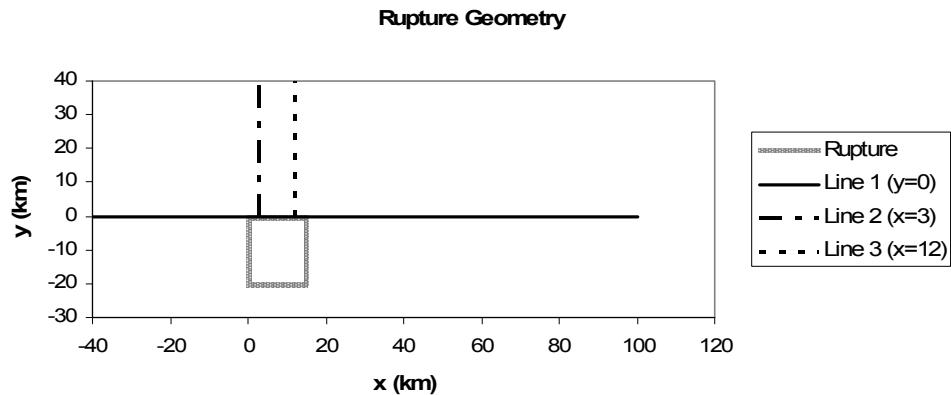

Fig. 3.13 Map view of example fault rupture.

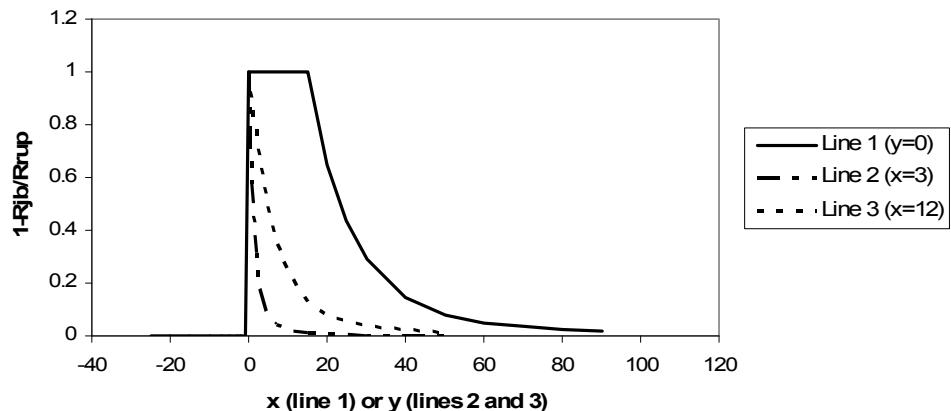

Fig. 3.14 Variation of the term $[1 - R_{JB} / R_{RUP}]$ with location for the three lines shown in Fig. 3.13. Top of rupture is at the ground surface at $x=0$.

The value of 0.001 km is added to provide numerical stability when R_{RUP} equals 0. Assuming the hanging-wall effect is a geometric effect, as the same size rupture is moved to deeper depths, we would expect the hanging-wall effect to be less. This trend has been observed in the PEER-NGA data and in the study by Chiou et al. (2000). The Z^2_{TOR} in $\sqrt{R_{JB}^2 + Z_{TOR}^2}$ is used to model the decrease in the hanging-wall effect with increasing depth of rupture.

The second term of Equation (3.7) modifies the third term to capture several additional geometric aspects of the hanging-wall effect. Examination of the simulation results presented in Chiou et al. (2000) and those conducted for the NGA project (Somerville et al. 2006) indicated that the hanging-wall effect decreases to near zero as one approaches the up-dip edge of the rupture (R_X approaches 0). To model this behavior, the $\tanh(R_X/c_{9a})$ function tapers the hanging-wall effect on and near the up-dip edge of rupture. The simulated data also show that the hanging-wall effect decreases with increasing dip angle. Assuming that the hanging-wall effect is a geometric effect, this trend with δ is expected. Figure 3.15 shows residuals for sites on the hanging wall of reverse faults ($R_{JB} = 0$) plotted versus δ . The data indicate increasing motion with decreasing δ , consistent with the trend seen in simulations. In Figure 3.15 the trend was modeled with linear functions $90^\circ - \delta$, $\cos(\delta)$, and $\cos^2(\delta)$. All three functions show a significant trend with the residuals, with $\cos^2(\delta)$ providing a slightly better fit than the other two models. Similar results were found for data from sites with $[1 - R_{JB} / R_{RUP}] > 0.8$ and for data from sites with $R_{JB} < 5$ km. We use $\cos^2(\delta)$ in our model to represent the dependence on δ . Finally, we expect that smaller overall ruptures would produce less effect than larger rupture, given the same values of R_{JB} and R_{RUP} . Previous implementations of the hanging-wall effect in empirical models have reduced the effect to 0 for magnitudes less than M 6. Equation (3.7), combined with the fact that the fault rupture width decreases as the magnitude decreases, automatically produces a decrease in the hanging-wall effect with decreasing magnitude.

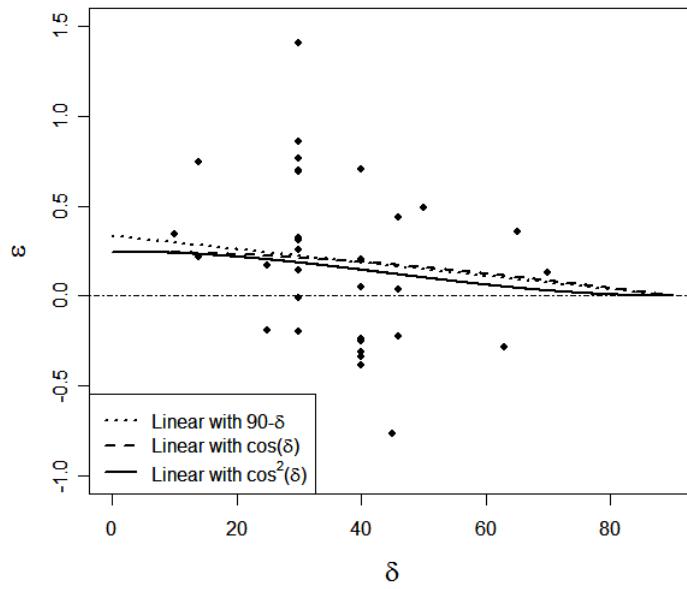

Fig. 3.15 Intra-event residuals from fitting a model without a hanging-wall term for sites with $R_{JB} = 0$ and $F_{HW} = 1$ plotted against fault dip, δ .

The behavior of f_{HW} defined in Equation (3.7) is illustrated in Figure 3.16 for three magnitudes and two values of Z_{TOR} . The plots show the value of f_{HW} for sites located directly above or down dip of the rupture surface. Note that the locations of the bottom edge of the ruptures correspond with the peaks in the f_{HW} curves.

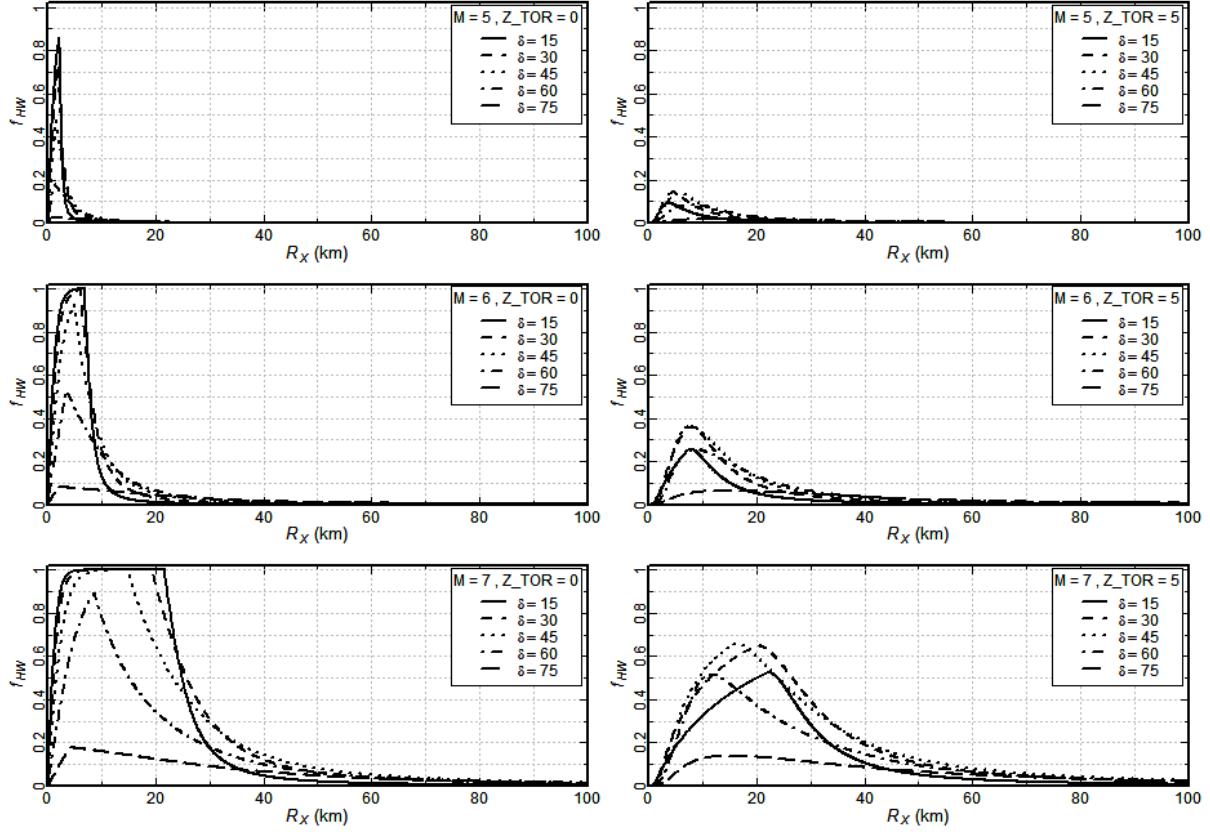

Fig. 3.16 Illustration of the hanging-wall geometric factor f_{HW} for sites located directly above or down dip of rupture plane. Left plots are for M 5, 6, and 7 earthquakes with $Z_{TOR} = 0$. Right plots are for M 5, 6, and 7 earthquakes with $Z_{TOR} = 5$ km. Note that locations of the bottom edges of ruptures correspond with peaks in f_{HW} curves.

3.4 SITE EFFECTS

3.4.1 Near-Surface Geology

The incorporation of the effects of near-surface geology or site classification has gone through an evolution in the past 10 years. At the beginning of this period, ground motion models typically contained a scaling parameter based on site classification (Boore et al. 1993), or presented different models for “rock” and “soil” sites (Campbell 1993; Sadigh et al. 1997). Classification of recording sites into rock or soil sites varied among investigators. Boore et al. (1997) introduced the explicit use of the average shear-wave velocity in the upper 30 meters, V_{S30} , in the ground motion model. Abrahamson and Silva (1997) building on an earlier model by Youngs (1993) introduced the explicit modeling of nonlinear site effects in the ground motion model.

The model we have developed for incorporating near-surface geology combines these concepts using the formulation:

$$\ln(y) = \ln(y_{ref}) + f_{site}(V_{S30}, y_{ref}, \eta) \quad (3.8)$$

Parameter y_{ref} is the population median motion on the reference site condition derived from the source and path scaling models described in the previous sections; see also Equation (3.12a) below. Parameter η is the earthquake effect term (also called the random-effect term), representing the deviation of the median reference motion for a given earthquake from the population median. Note that y_{ref} and η are combined to form the event-specific median reference motion $y_{ref} e^{\eta}$ that drives the nonlinear part of f_{site} (see Eq. 3.12.b and explanation in Chapter 4). In the discussions below, we sometimes drop the event term η and the word ‘event-specific’ for convenience of discussion.

The reference site V_{S30} was chosen to be 1130 m/sec because it is expected that there will not be significant nonlinear site response at this velocity. In addition, there are very few data with values of V_{S30} greater than 1100 m/sec in the PEER-NGA database. The reference motion is defined to be the spectral acceleration at the spectral period of interest for two reasons. Bazzurro and Cornell (2004) indicate that the spectral acceleration at spectral period T is “the single most helpful parameter” for the prediction of site amplification at that period. In addition, estimation of the coefficients of ground motion model is performed using random (mixed) effects regression in which the reference motion includes the random event term. Use of the reference spectral acceleration at period T to estimate surface ground motions at the same period eliminates the need to include the correlation in the random effects between those at period T and those at another period or pga .

The function form for the site response model f_{site} with y_{ref} computed at V_{S30} equal to 1130 m/sec is given by:

$$\begin{aligned}
f_{site}(V_{S30}, T, y_{ref}) &= a(V_{S30}, T) + b(V_{S30}, T) \ln \left[\frac{y_{ref}(T) + c(T)}{c(T)} \right] \\
a(V_{S30}, T) &= \phi_1(T) \ln \left[\frac{V_{S30}}{1130} \right] \\
b(V_{S30}, T) &= \phi_2(T) [\exp\{\phi_3(T) \times (\min(V_{S30}, 1130) - 360)\} - \exp\{\phi_3(T) \times (1130 - 360)\}] \\
c(T) &= \phi_4(T)
\end{aligned} \tag{3.9}$$

The interpretation of coefficients a , b , and c is as follows (Fig. 3.17). Coefficient a represents the linear soil amplification factor that occurs at a small level of y_{ref} . It is modeled as a linear function of $\ln(V_{S30})$, consistent with previous representations (Boore et al. 1997). Coefficient c represents the reference ground motion level in the middle of the transition from linear to nonlinear behavior. Coefficient b represents the nonlinear behavior in terms of the rate of decrease in site amplification, f_{site} , with increasing amplitude of y_{ref} . In general, a stronger nonlinearity in soil response corresponds to a more negative value for b (stronger dependence on y_{ref}). It is expected that the degree of nonlinearity is a function of the stiffness of the site soils, and this dependence is represented by making b a function of V_{S30} . The last term of the equation for b is used to produce linear response ($b = 0$) for $V_{S30} = 1,130$ m/sec. Figure 3.18 shows several examples of f_{site} obtained from fitting the PEER-NGA data.

The functional form of Equation (3.9) is able to represent other models of nonlinear site response, such as that developed by Choi and Stewart (2005) as well as the results of site response analyses conducted for the NGA project by Silva (2008; Walling et al. 2008). The ability of Equation (3.9) to represent nonlinear soil response derived from Silva's simulations is illustrated in Figures 3.19–3.20. Figure 3.19 shows soil amplification factors for pga derived from Silva's (2008) simulations. Two soil property models were used by Silva (2008; Walling et al. 2008), the EPRI (1993) set of soil modulus and damping relationships and the less nonlinear Peninsular Range set developed by Silva et al. (1996). The solid lines shown on the figure are the result of fitting Equation (3.9) to the combined amplification factors for the two soil model sets and indicate that the function form can well represent the behavior implied by nonlinear (equivalent-linear) soil response. Figure 3.20 shows the values of parameters a and b derived from the results of Silva (2008). The dashed lines show that the function forms for a and b in Equation (3.9) provide a good match to the site response results.

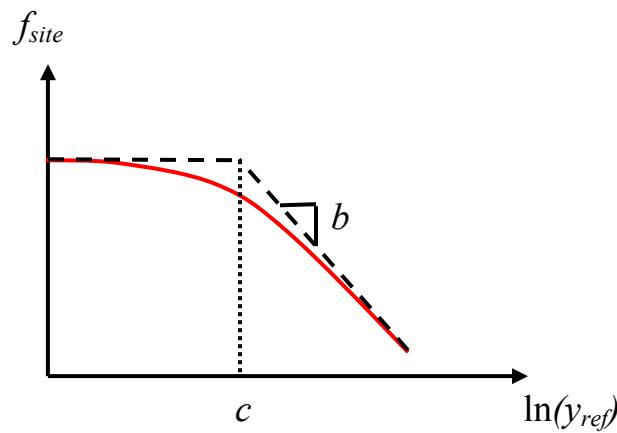

Fig. 3.17 Illustration of functional form for soil amplification effect as a function of $\ln(y_{ref})$.

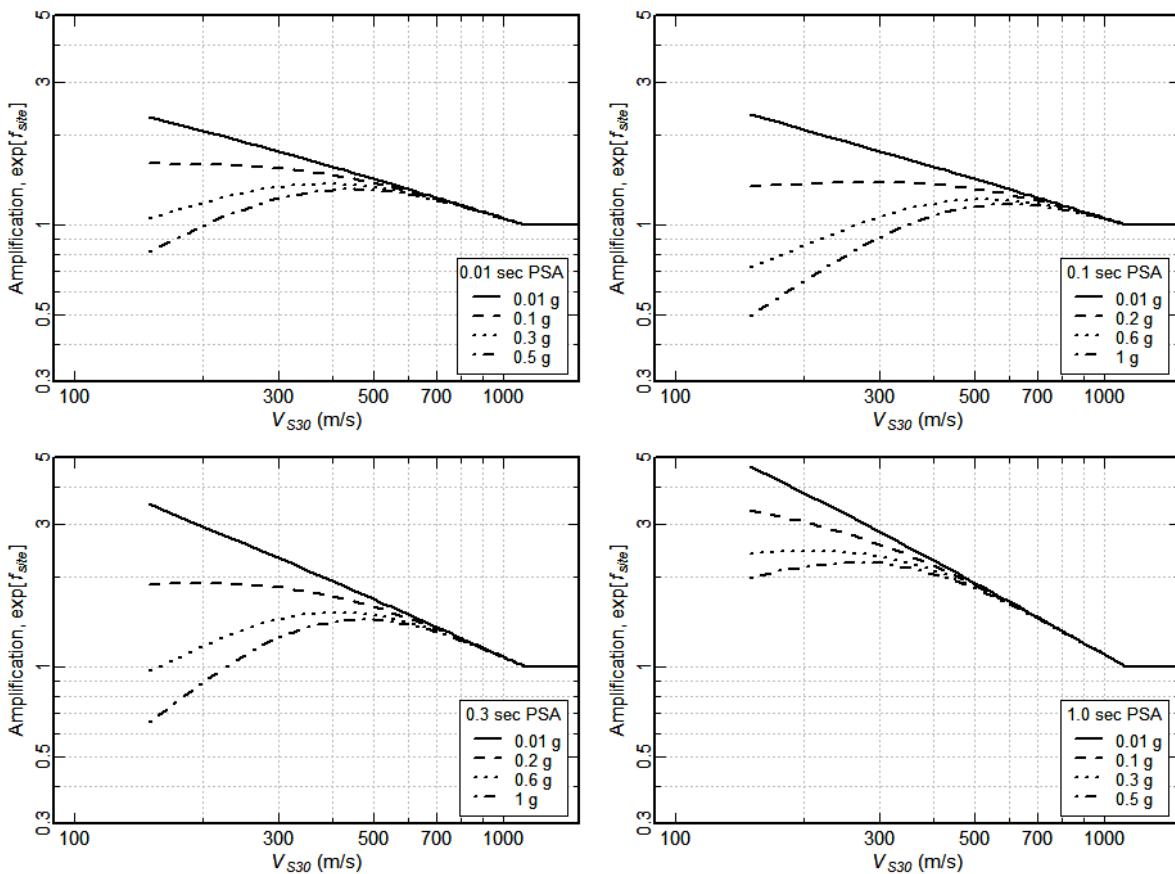

Fig. 3.18 Example site amplification as a function of spectral period, V_{S30} , and level of reference *PSA*.

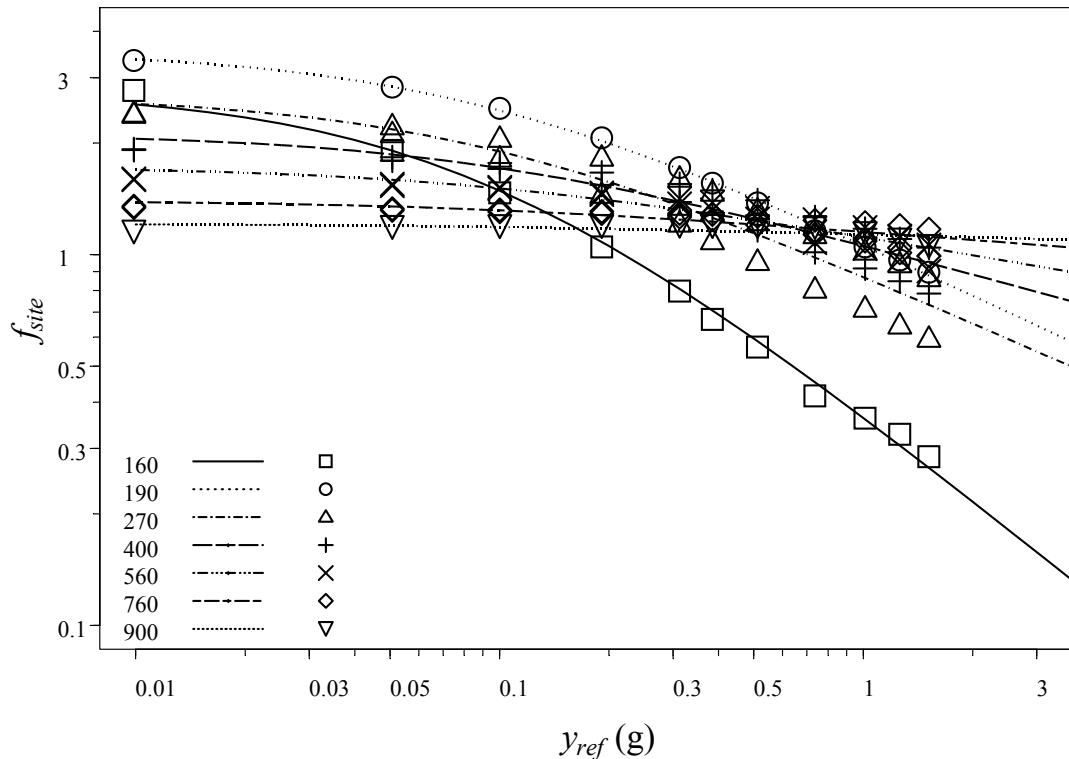

Fig. 3.19 Soil amplification for pga as a function of rock motion (y_{ref}) from 1-D equivalent linear site response analyses (Silva 2008).

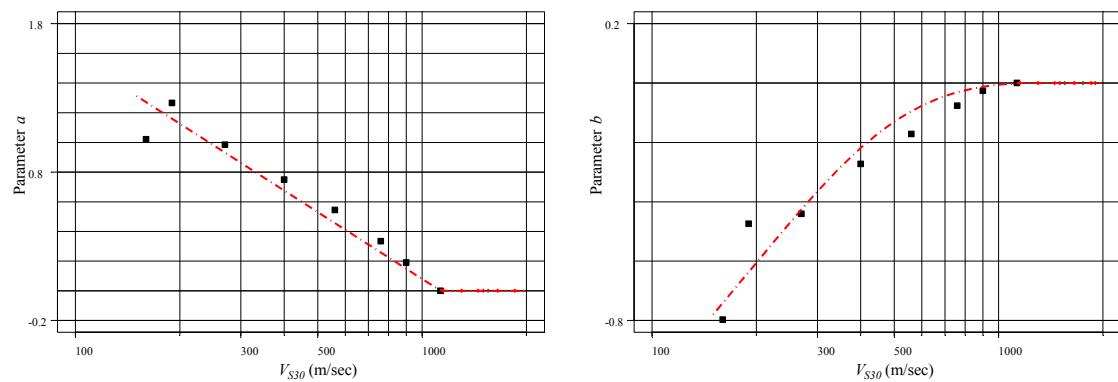

Fig. 3.20 Coefficients a and b derived from 1-D site response results of Silva (2008). Dashed lines represent fits using functional form in Eq. (3.9).

Choi and Stewart (2005) developed a model for the dependence of nonlinear soil amplification on V_{S30} and the level of input rock pga . Figure 3.21 compares the variation of the parameter b computed from their models with results obtained from fitting Equation (3.9) to the PEER-NGA pga data selected for use in this study. The functional form of Equation (3.9) provides a good match to the general behavior of the models developed by Choi and Stewart (2003).

To demonstrate the validity of Equation (3.9) in modeling the nonlinear soil amplification implied by the NGA data, we compute the intra-event residuals with respect to our final NGA model without the soil amplification effect (i.e., for a V_{S30} of 1130 m/sec). The residuals computed this way can be interpreted as soil amplification data relative to the event-specific median reference motion. The residuals for PSA at 0.2-sec period, grouped by the level of event-specific median reference motion, are plotted against V_{S30} in Figure 3.22. The average soil amplification factor predicted from our final NGA model is also shown in Figure 3.22 as the dot-dashed curve. For low- V_{S30} recordings subjecting to large reference motion, there are clearly defined deviations from the linear soil amplification (shown as the solid line) in a manner that is consistent with Equation (3.9).

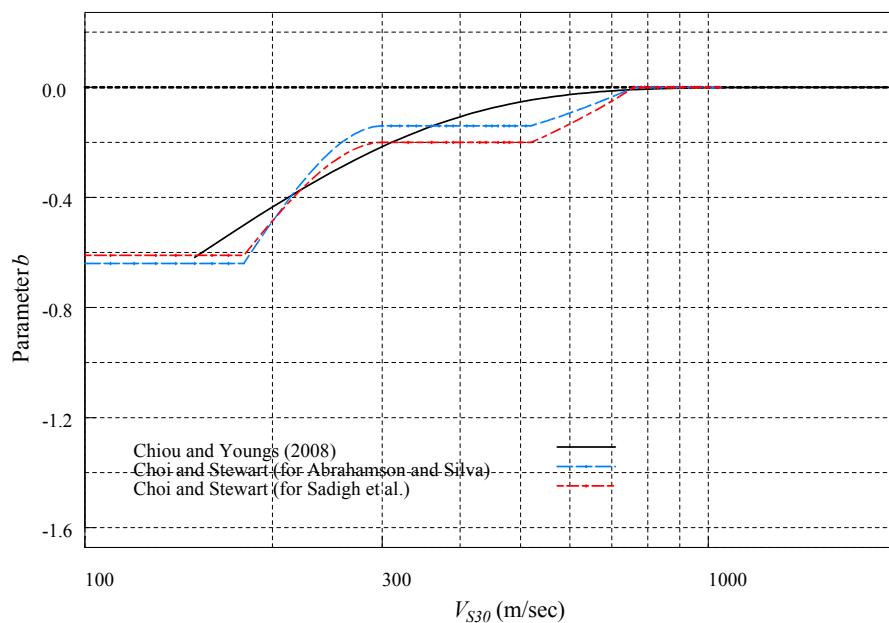

Fig. 3.21 Comparison of parameter b dependence on V_{S30} obtained by Choi and Stewart (2003) (dashed curve—Abrahamson and Silva 1997, reference motions; dot-dashed curve—Sadigh et al. 1997, reference motions) with trend obtained in this study from PEER-NGA data (solid line).

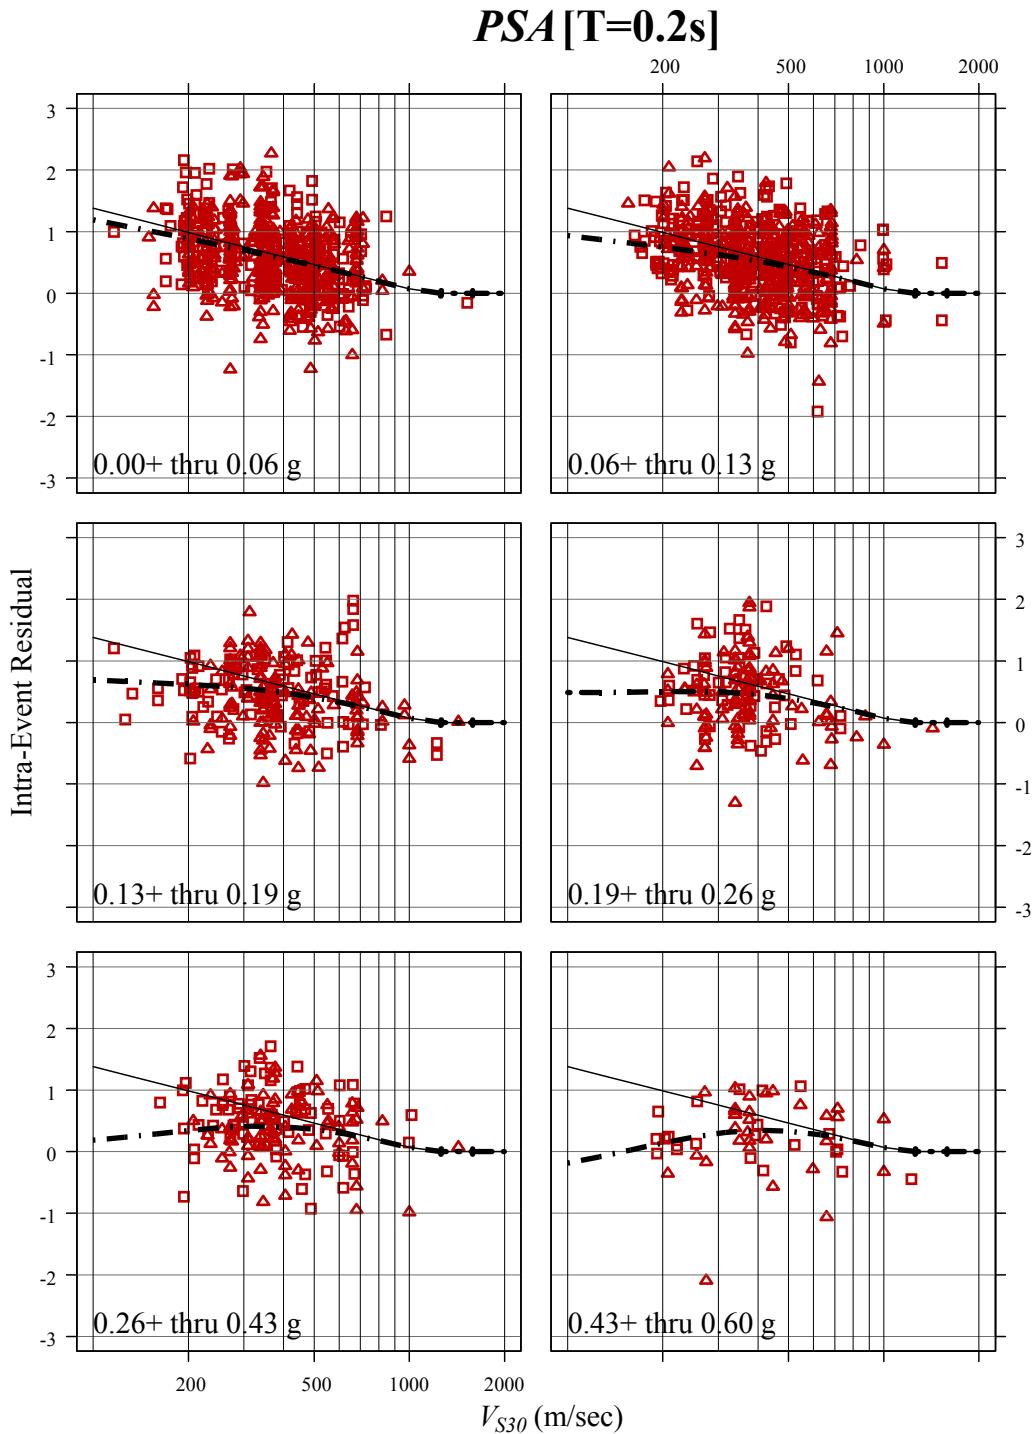

Fig. 3.22 Intra-event residuals plotted as a function of V_{S30} . These residuals are computed using the final NA model without the soil amplification effect. Square and triangle indicate data whose V_{S30} is measured and inferred, respectively. The dot-dashed curve is the predicted nonlinear soil amplification factor and the solid line is the predicted linear amplification factor. The range of event-specific median reference motion ($y_{ref} \exp(\eta)$) is indicated in the lower left corner of each plot.

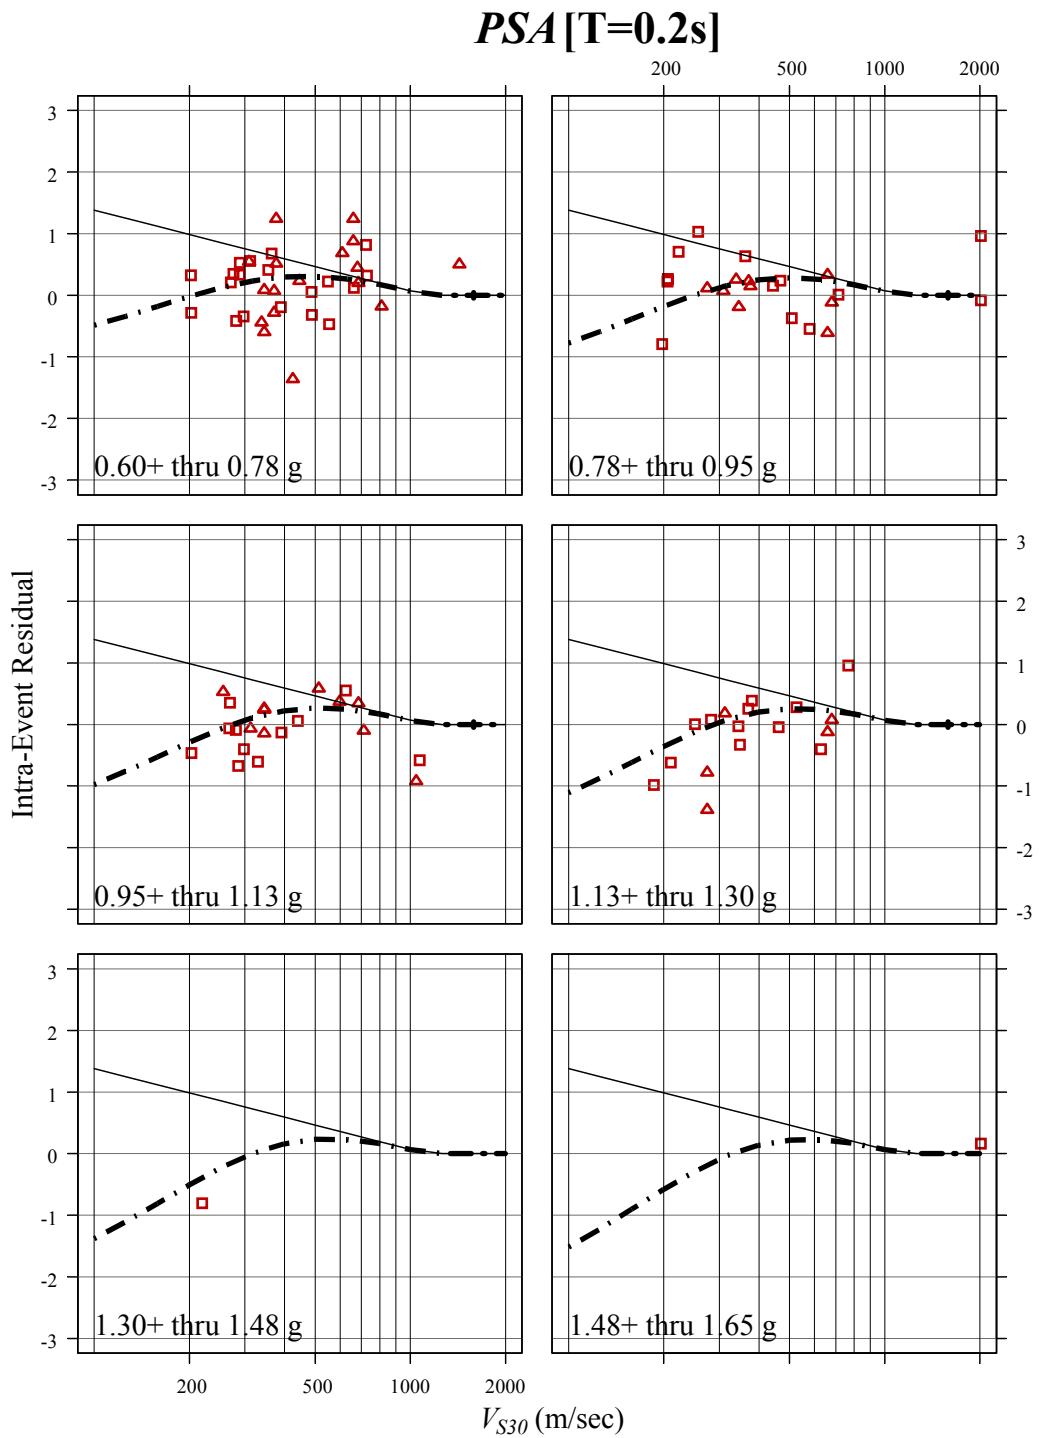

Fig. 3.22—Continued

3.4.2 Sediment Thickness

Most empirical ground motion models have used either a simple classification scheme (Abrahamson and Silva 1997, Sadigh et al. 1997) or V_{S30} (Boore et al. 1997) to represent soil amplification in ground motions. The success of these models suggests that surface geology or V_{S30} is often highly correlated with other site properties important to the quantification of site amplification. However, a single parameter such as V_{S30} cannot be expected to completely represent the effects of local site conditions on earthquake ground motions. Campbell (1989) found that adding a parameter for depth to basement rock improved the predictive ability of empirical ground motion models. Other investigators had proposed including basin depth to improve empirical ground motion models (Joyner 2000; Field 2000; Choi et al. 2005). In addition, successful numerical modeling of ground motions on a variety of site conditions typically incorporate a much more detailed characterization of the site velocity profile (Silva et al. 1996; Boore and Joyner 1997).

To improve the modeling in environments such as deep sedimentary basins, we add sediment thickness as a second predictor of site amplification. We define sediment thickness as the depth to a material (bedrock) with a shear-wave velocity (V_s) of 1 km/sec or greater. Shear-wave velocities of 1.5 km/sec and 2.5 km/sec have also been used to define the appropriate velocity horizon (Field 2000; Day et al. 2006). We prefer 1 km/sec because it is similar to values commonly used in practice for rock. It is also close to the reference V_{S30} (1130 m/sec) used in the V_{S30} -scaling of soil amplification. Finally, the depth to this velocity is more likely to be available as a part of site characterization than depths to higher velocity horizons. Boreholes at 54 sites in the PEER-NGA database penetrated the $V_s = 1$ km/sec horizon.

For the majority of NGA strong-motion sites there is a correlation between V_{S30} and $Z_{1.0}$. The intent of Equations (3.10) and (3.11), described below, is to capture departures from the general V_{S30} scaling defined by Equation (3.9).

3.4.2.1 Deep Sediment Sites

Figure 3.23 shows residuals from an interim model without a sediment depth effect plotted versus $Z_{1.0}$ for sites in the PEER-NGA database. We find that the trend can be adequately modeled by the functional form:

$$\ln(y) \propto \phi_5 \left(1 - \frac{1}{\cosh[\phi_6 \times \max(0, Z_{1.0} - \phi_7)]} \right) \quad (3.10)$$

This functional form produces behavior similar to the model developed by Day et al. (2006, 2008), allowing for the fact that Day et al. (2006) modeled the combined effect of V_{S30} and sediment depth using only sediment depth, while the residuals shown in Figure 3.23 are computed from a model that incorporates V_{S30} scaling. The main difference from the functional form of Day et al. (2006, 2008) is that we allow the affected $Z_{1.0}$ range ($Z_{1.0} > \phi_7$) to vary with spectral period, motivated by observing this trend in the residuals (Fig. 3.23). The fitted models are also shown on Figure 3.23.

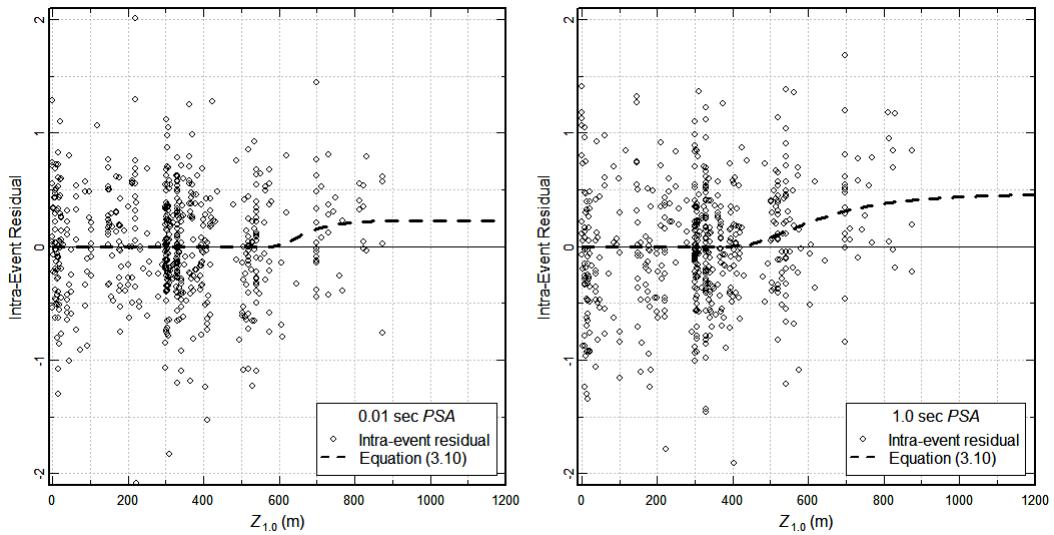

Fig. 3.23 Intra-event residuals plotted against measured $Z_{1.0}$ for 0.01-sec and 1.0-sec PSA. Dashed lines show fits to the residuals using Eq. (3.10).

3.4.2.2 Shallow Sediment Sites

Focusing on the shallow $Z_{1.0}$ range, we find negative average residuals in the $Z_{1.0}$ range of 5–25m for spectral periods between 0.3 and 1 sec and positive residuals at other periods (Fig. 3.24). Because of the limited data available to determine the $Z_{1.0}$ at which average residual is back to 0, we judged a value of 40 m to be reasonable, and use the following functional form to model the $Z_{1.0}$ effect on shallow rock sites:

$$\ln(y) \propto \frac{\phi_8}{\cosh(0.15 \times \max(0, Z_{1.0} - 15))} \quad (3.11)$$

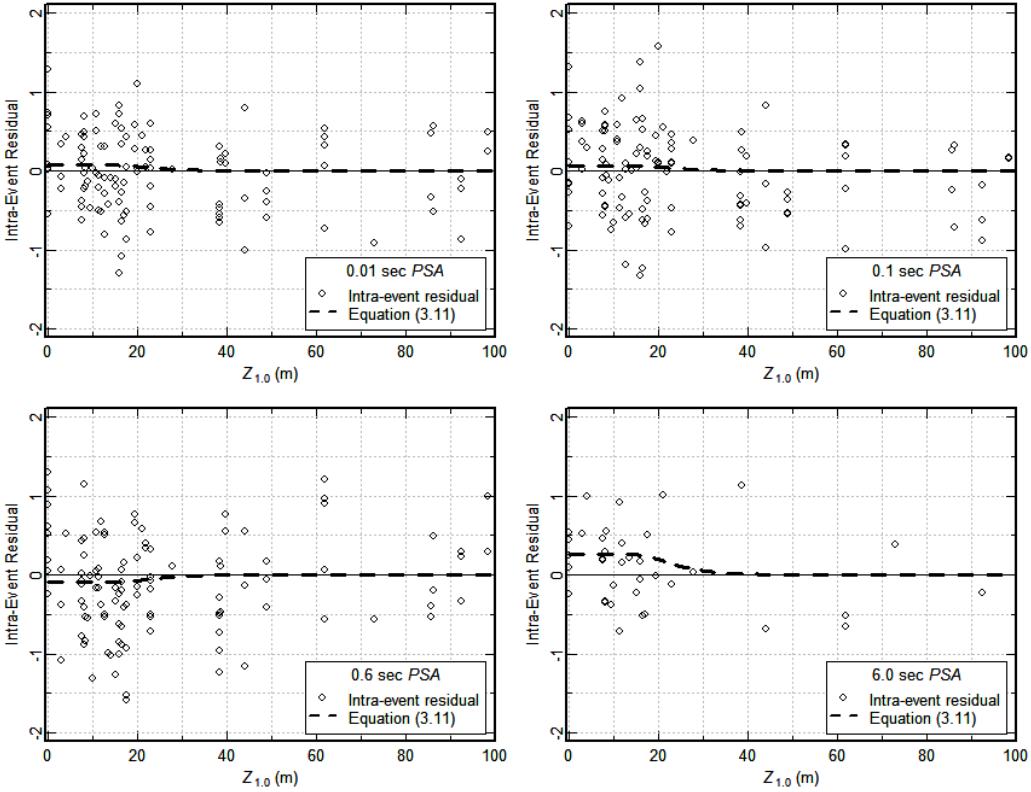

Fig. 3.24 Intra-event residuals plotted against $Z_{1.0}$ for shallow sediment sites for spectral periods of 0.01, 0.10, 0.6, and 6.0 sec. Dashed lines show fits to the residuals using Eq. (3.11).

3.5 COMPLETE MODEL FOR ESTIMATING GROUND MOTIONS

The above considerations are combined to form the final complete model formulation:

$$\begin{aligned}
 \ln(y_{ref_i}) = & c_1 + [c_{1a}F_{RVi} + c_{1b}F_{NMI} + c_7(Z_{TORi} - 4)](1 - AS_i) + [c_{10} + c_{7a}(Z_{TORi} - 4)]AS_i \\
 & + c_2(\mathbf{M}_i - 6) + \frac{c_2 - c_3}{c_n} \ln(1 + e^{c_n(c_M - \mathbf{M}_i)}) \\
 & + c_4 \ln[R_{RUPij} + c_5 \cosh\{c_6 \max(\mathbf{M}_i - c_{HM}, 0)\}] \\
 & + (c_{4a} - c_4) \ln\left(\sqrt{R_{RUPij}^2 + c_{RB}^2}\right) \\
 & + \left\{ c_{\gamma 1} + \frac{c_{\gamma 2}}{\cosh[\max(\mathbf{M}_i - c_{\gamma 3}, 0)]} \right\} R_{RUPij} \\
 & + c_9 F_{HWij} \tanh\left(\frac{R_{Xij} \cos^2 \delta_i}{c_{9a}}\right) \left\{ 1 - \frac{\sqrt{R_{JBij}^2 + Z_{TORi}^2}}{R_{RUPij} + 0.001} \right\}
 \end{aligned} \tag{3.12a}$$

and

$$\begin{aligned}
 \ln(y_{ij}) = & \ln(y_{ref_{ij}}) + \phi_1 \cdot \min\left(\ln\left(\frac{V_{S30j}}{1130}\right), 0\right) \\
 & + \phi_2 \left\{ e^{\phi_3(\min(V_{S30j}, 1130)-360)} - e^{\phi_3(1130-360)} \right\} \ln\left(\frac{y_{ref_{ij}} e^{\eta_i} + \phi_4}{\phi_4}\right) \\
 & + \phi_5 \left(1 - \frac{1}{\cosh[\phi_6 \cdot \max(0, Z_{1.0} - \phi_7)]}\right) + \frac{\phi_8}{\cosh[0.15 \cdot \max(0, Z_{1.0} - 15)]} + \eta_i + \varepsilon_{ij}
 \end{aligned} \tag{3.12b}$$

The predictor variables for fixed effects are:

M = Moment magnitude

R_{RUP} = Closest distance to the rupture plane (km)

R_{JB} = Joyner-Boore distance to the rupture plane (km)

R_X = Site coordinate (km) measured perpendicular to the fault strike from the surface projection of the up-dip edge of the fault rupture, with the down-dip direction being positive (See Fig. 3.12)

F_{HW} = Hanging-wall flag: 1 for $R_X \geq 0$ and 0 for $R_X < 0$

δ = Fault dip angle

Z_{TOR} = Depth to top of rupture (km)

F_{RV} = Reverse-faulting flag: 1 for $30^\circ \leq \lambda \leq 150^\circ$ (combined reverse and reverse-oblique), 0 otherwise; λ is the rake angle.

F_{NM} = Normal faulting flag: 1 for $-120^\circ \leq \lambda \leq -60^\circ$ (excludes normal-oblique), 0 otherwise.

AS = Aftershock flag: 1 if the event is an aftershock, 0 otherwise

V_{S30} = Average shear-wave velocity for top 30 m (m/s)

$Z_{1.0}$ = Depth to shear-wave velocity of 1.0 km/s (m).

The variability in ground motion is represented in Equation (3.12b) by random variables η_i and ε_{ij} . Models for the variance of these two random variables are described in the next Chapter. Note that the random earthquake effect η_i appears on the 3rd line of Equation (3.12b) as well as inside the logarithmic function on the 2nd line. The reason for this formulation is also explained in the next Chapter.

4 Mixed-Effects Model Formulation and Variance Model Incorporating Nonlinear Soil Response

Equations (3.12a) and (3.12b) are a mixed-effects regression model (Brillinger and Preisler 1984; Abrahamson and Youngs 1992; Pinheiro and Bates 2000). The mixed-effects model incorporates fixed effects to model the expected amplitude of $\ln(y)$ as a function of magnitude, distance, V_{S30} , etc., and random effects to represent a random shift of all observations for an individual earthquake from this expected amplitude. Just as fixed effects described in the previous Chapter are grouped into three components representing the physical processes of source, path, and site, the random errors in our mixed-effects model are divided into four independent components of source (η_i), path (ε_{Pij}), site (ε_{Sj}), and the remaining modeling errors ε_{Xij} . The first component, η_i , represents the random earthquake effect (Brillinger and Preisler 1984; Abrahamson and Youngs 1992). This random effect, also called the inter-event residual, is attributed to the individual earthquake such that all recordings from the i -th earthquake deviate from the global population mean, μ , by a value η_i . The inter-event residuals are assumed to be independent and normally distributed with a zero mean and a variance τ^2 .

Each of the three remaining error components is also assumed to be independent and normally distributed with a zero mean and variances σ_P^2 , σ_S^2 , and σ_X^2 , respectively. In practice, these three error components are lumped into a combined intra-event residual ε_{ij} . Individual recording at station j from the i -th earthquake deviate from the earthquake-specific mean, $\mu+\eta_i$, by intra-event residuals, ε_{ij} , that are assumed to be normally distributed with variance σ^2 . In the following we show that due to nonlinear soil response the variance σ^2 is a function of soil nonlinearity.

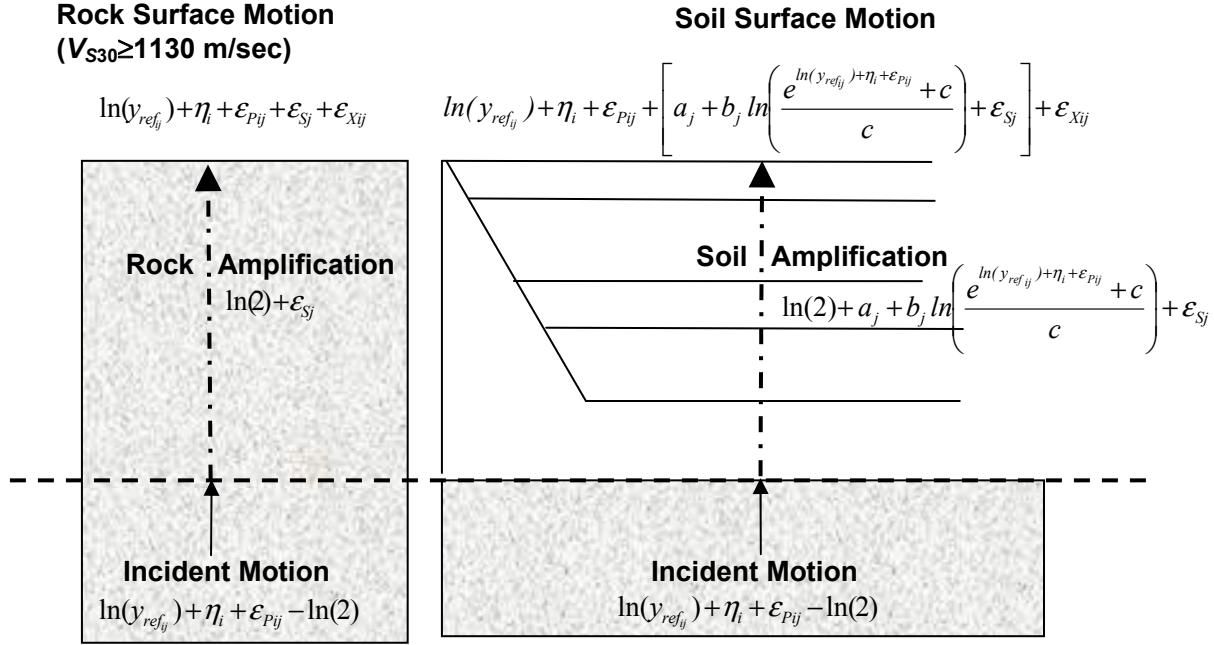

Fig. 4.1 Illustration showing framework of rock surface motion, soil amplification, and soil surface motion, assuming ϵ_s has the same probability density function for rock and soil surface motions.

Using the formulation of soil amplification described in Section 3.4.1 and the geotechnical framework illustrated in Figure 4.1, the surface motion $\ln(y_{ij})$ is written as:

$$\ln(y_{ij}) = \ln(y_{refj}) + \eta_i + \epsilon_{Pij} + a_j + b_j \ln\left(\frac{e^{(\ln(y_{refj}) + \eta_i + \epsilon_{Pij})} + c}{c}\right) + \epsilon_{Sj} + \epsilon_{Xij}, \quad (4.1)$$

where y_{refj} is the reference motion specified by Equation (3.12a). The sum of $\ln(y_{refj})$, the earthquake term η_i , and the path error ϵ_{Pij} [the first three terms of Eq. (4.1)] represents the logarithm of the incident motion to the bedrock-soil column interface beneath a site. This incident motion drives the soil column and determines the average soil amplification factor for surface motion. Note that the intra-event components ϵ_{Sj} and ϵ_{Xij} are not part of the incident motion and hence they do not affect the average soil amplification factor.

Though Equation (4.1) represents fully our conceptual model of nonlinear soil amplification, its use in regression analysis of empirical data is made difficult by the lack of repeatedly sampled paths and limited repeatedly sampled sites; and by the unavailability of a

statistical inference method capable of handling the complicated data structure induced by the path error ε_{Pij} being part of the incident motion that drives the soil nonlinear response. To get around these difficulties, we move ε_{Pij} outside of $\ln[(y_{ref_{ij}} e^{\eta_i + \varepsilon_{Pij}} + c) / c]$ by replacing the logarithm with the first two terms of its Taylor series expansion (a first-order approximation):

$$\ln(y_{ij}) = \ln(y_{ref_{ij}}) + \eta_i + \varepsilon_{Pij} + a_j + b_j \left(\ln\left(\frac{y_{ref_{ij}} e^{\eta_i} + c}{c}\right) + \frac{y_{ref_{ij}} e^{\eta_i}}{y_{ref_{ij}} e^{\eta_i} + c} \varepsilon_{Pij} \right) + \varepsilon_{Sj} + \varepsilon_{Xij} \quad (4.2)$$

Combining the error terms (not including η_i) into a single intra-event error ε_{ij} produces:

$$\varepsilon_{ij} = \varepsilon_{Pij} + \left[b_j \frac{y_{ref_{ij}} e^{\eta_i}}{y_{ref_{ij}} e^{\eta_i} + c} \right] \varepsilon_{Pij} + \varepsilon_{Sj} + \varepsilon_{Xij} \quad (4.3)$$

Substituting Equation (4.3) into (4.2), we obtain the mixed-effects regression model that Equation (3.12b) used in our regression analysis:

$$\ln(y_{ij}) = \ln(y_{ref_{ij}}) + \eta_i + a_j + b_j \ln\left(\frac{y_{ref_{ij}} e^{\eta_i} + c}{c}\right) + \varepsilon_{ij} \quad (4.4)$$

In Equation (4.4) the effect of η_i on nonlinear soil de-amplification is being carried exactly. The approximate effect of ε_{Pij} on soil nonlinear response is now part of the intra-event error ε_{ij} , the 2nd term of Equation (4.3).

From Equation (4.3), the variance of the intra-event error is given by:

$$\sigma^2 = \sigma_S^2 + \sigma_X^2 + \left(1 + b_j \frac{y_{ref_{ij}} e^{\eta_i}}{y_{ref_{ij}} e^{\eta_i} + c} \right)^2 \sigma_P^2 \quad (4.5)$$

It is important to note that the intra-event variance decreases with decreasing value of $|1 + b_j y_{ref_{ij}} e^{\eta_i} / (y_{ref_{ij}} e^{\eta_i} + c)|$. Therefore, the introduction of nonlinear soil response into our ground

motion prediction equation directly leads to a heteroscedastic (non-constant) intra-event variance that is dependent on the values of b (hence, V_{S30}), $y_{ref} \exp(\eta)$, and c . The variable $NL_{ij} = [b_j y_{ref_{ij}} e^{\eta_i} / (y_{ref_{ij}} e^{\eta_i} + c)]$, which is always less than or equal to 0 because the sign of b_j is negative, can be interpreted as a measure of soil nonlinearity affecting a strong-motion recording, with a value of 0 indicating linear soil response.

One way to explore the degree of intra-event heteroscedasticity in our NGA data set is to plot intra-event residuals against $1+NL_{ij}$. Intra-event residuals for the spectral period of 0.1 sec are plotted against $(1+NL_{ij})$ in Figure 4.2. The quantities b_j , η_i , and c needed for the calculation of NL_{ij} are taken from the fitted model for $T=0.1$ sec. To help illustrate the variation of intra-event variance as a function of $(1+NL_{ij})$, intra-event standard errors computed for several non-overlapping intervals of $(1+NL_{ij})$ are plotted as solid squares. The dashed curves in Figure 4.2 show the fitted variance model based on Equation (4.5). They clearly show a dependency of intra-event variance on $(1+NL_{ij})$ that is consistent with Equation (4.5).

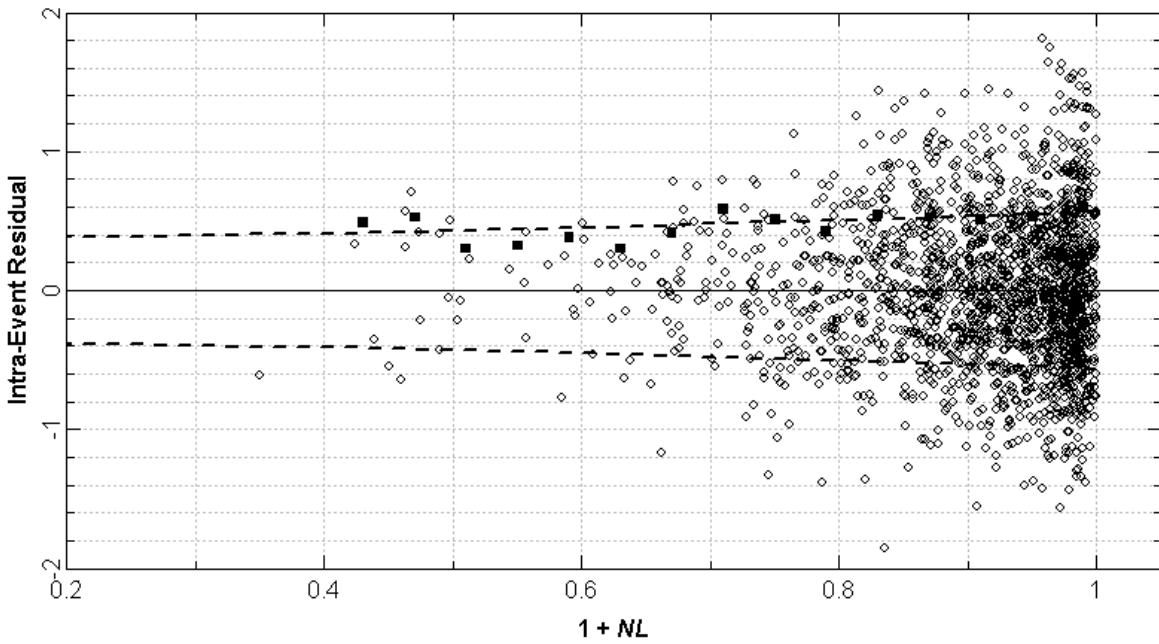

Fig. 4.2 Intra-event residuals for 0.1-sec *PSA* plotted against variance covariate ($1+NL$).
Solid squares are bin estimates of standard deviation; dashed lines show fitted variance function.

5 Model Development

5.1 ESTIMATION OF FIXED-EFFECTS COEFFICIENTS

The fixed-effects coefficients of the ground motion model [Eqs. (3.12a) and (3.13b)] were estimated using the nonlinear mixed-effects method *nlme* (Pinheiro and Bates 2000) implemented in the statistical packages **S-PLUS** and **R**. The coefficients were developed through an iterative process of performing regressions for the entire spectral period range with some parts of the model fixed, developing smoothing models for these coefficients with period, and then repeating the analysis to examine the variation of the remaining coefficients. All analyses were performed using the selected PEER-NGA data truncated at a maximum distance of $R_{RUP} = 70$ km. The resulting coefficients are listed in Tables 5.1–5.3 for selected spectral periods. Appendix H lists the complete set of coefficients for 105 spectral periods.

After extensive exploratory analysis of the data, we concluded that the PEER-NGA data set does not sample a sufficiently wide range of motion and V_{S30} to allow the simultaneous estimation of all 3 nonlinear soil parameters (ϕ_2 , ϕ_3 , and ϕ_4). We thus decided to fix ϕ_4 through other supporting information in the initial steps of regressions. Both our preliminary analysis of the PEER-NGA data and analyses of the simulated soil amplification factors from Silva (2008) and Bazzurro and Cornell (2004) suggested that ϕ_4 is about 0.1g in the case of *pga*. The empirical study of Choi and Stewart (2005) also indicated that 0.1g is a viable value for ϕ_4 . We thus fix *pga*'s ϕ_4 at 0.1g. To fix ϕ_4 of other periods, we anchored the rock spectral shape of **M** 6.5 at 10 km (Silva et al. 1997) at 0.1g *pga*. The remaining two nonlinear parameters ϕ_2 and ϕ_3 were then estimated by the regression of data. Once the values of ϕ_2 and ϕ_3 were determined, we revised the estimate of ϕ_4 with coefficients ϕ_2 and ϕ_3 fixed to their estimated values. This process was repeated a few times. The final ϕ_4 for *pga* is slightly larger than 0.1g.

Coefficient c_{1a} (reverse-faulting effect) was found to decrease with increasing spectral period, becoming 0 at a period of 2.0 sec and then decreasing to about -0.1 at long periods. This is consistent with the trends observed in previous empirical models (Abrahamson and Silva 1997; Campbell and Bozorgnia 2003; the soil model of Sadigh et al. 1997). At high frequency, the positive c_{1a} value is consistent with an interpretation of higher stress drops (stress parameters) for reverse-faulting earthquakes than for strike-slip earthquakes. However, the negative value of c_{1a} at long periods is not consistent with this concept, indicating that other factors may also be influencing the difference between the motions produced by the two styles of faulting. For normal faulting, the value of c_{1b} was approximately -0.25 for short-period *PSA* and decreased in absolute value as the spectral period decreased. For spectral periods greater than about 1.0 sec, the value of c_{1b} becomes very uncertain. If one speculates that the negative value of c_{1a} for reverse-faulting earthquakes at long periods is due to more compact dip-slip earthquakes being less efficient at producing long-period motions than long strike-slip earthquakes, then perhaps the values of c_{1a} and c_{1b} should be similar in this period range. We have made this assumption in developing the period dependence of c_{1b} .

The estimated values of coefficient c_1 exhibited noticeable steps at periods of 0.8, 1.1, 1.6, 4, and 8 sec (Fig. 5.1). These steps occur at spectral periods where there are large reductions in the number of usable data (see Fig. 2.7), defined by the record's minimum usable frequency (Chiou et al. 2008). This suggested that the estimated values of c_1 may be biased by the systematic removal of weaker motions from the data set, which would tend to leave larger ground motion amplitudes in the remaining data. To correct this bias and to smooth c_1 , we imposed a smooth variation in the slope of c_1 with respect to period. The slope of c_1 was computed numerically and is shown in Figure 5.2. We examined the shapes of resulting displacement spectra for large-magnitude earthquakes ($M \geq 6.5$) to verify that constant

displacement is reached at spectral periods that are consistent with the model presented in BSSC (2004). The difference between the values of c_1 obtained from regression and the smoothed values reported after bias adjustment was incorporated into the assessment of the inter-event variance. The estimated values of c_1 before smoothing/bias correction are listed in Appendix H.

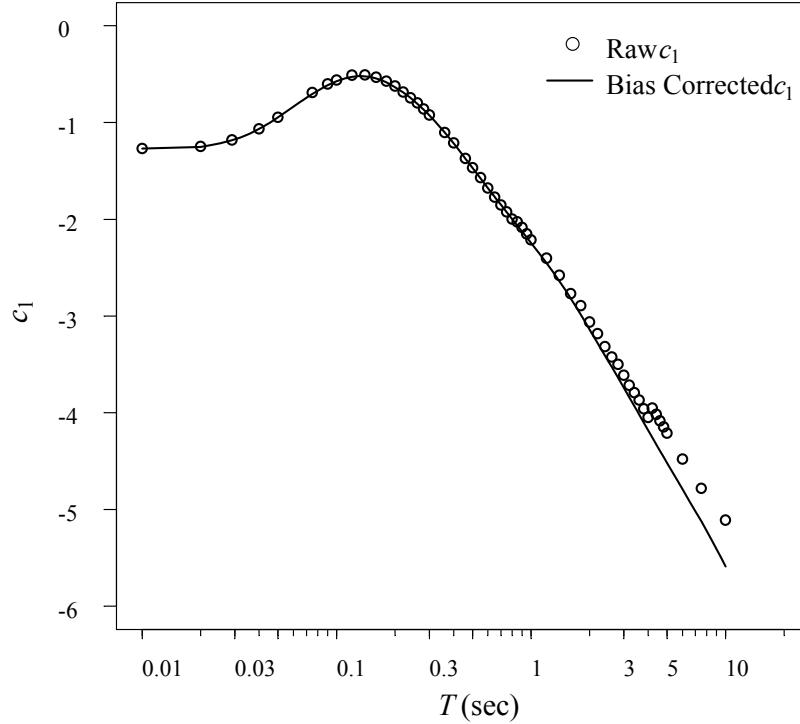

Fig. 5.1 Variation of coefficient c_1 with spectral period. Solid curve is c_1 after bias adjustment.

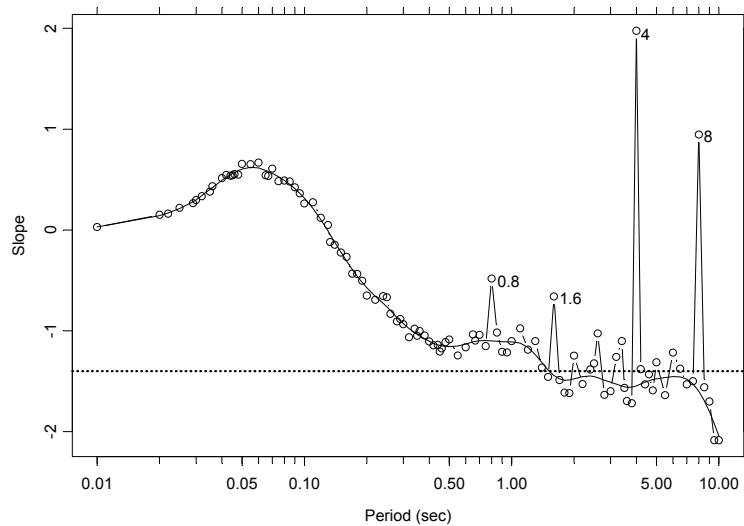

Fig. 5.2 Variation of the derivative of coefficient c_1 with respect to spectral period. Solid curve is smoothed derivative.

5.2 VARIANCE MODEL

During the first stages of model development, the results suggested that the residual standard errors did not depend upon earthquake magnitude, in contrast to the previous Sadigh et al. (1997) models. This was based on visual inspection of the residuals. However, statistical analysis of the residuals indicated that a statistically significant dependence on magnitude is present, although the amplitude of the effect is less than that found by Sadigh et al. (1997). The employed statistical test followed that used by Youngs et al. (1995). We first computed the log-likelihood for a model assuming magnitude-independent variance terms and after that for another model with the trilinear magnitude-dependent variance used by Youngs et al. (1995). We then used the likelihood ratio test to check the significance of the increase in log-likelihood found assuming magnitude-dependent variance. Magnitude-dependence in the variance was found to be statistically significant (p -values < 0.05) for periods up to about 1 sec. For longer periods the results showed less statistical significance, but at the same time there is a large reduction in the size of the data set, particularly in data from smaller-magnitude earthquakes.

We performed two additional checks on possible contributions to the observed magnitude dependence. We found that value of the intra-event standard deviation for the aftershock data is approximately 0.08 larger than that for the main shock data. When this was accounted for in the variance model, magnitude-dependence in the main-shock residuals was still found to be statistically significant. Similar estimates of inter-event variability were obtained for main shocks and aftershocks. Secondly, the reduction in intra-event variance due to nonlinear soil response could also contribute to the observed magnitude dependence, as larger earthquakes tend to produce larger motions, and thus induce greater nonlinear response. This effect was explored by Youngs et al. (1995), who found that it was not a major contributing factor. We tested the influence of soil nonlinearity by comparing the log-likelihoods obtained for data sets restricted to nonlinearity factors $NL > -0.15$ and again found that magnitude-dependence of the variance terms is statistically significant over much of the period range. Restricting the degree of nonlinearity further to $NL > -0.05$ resulted in greatly reducing the size of the data set to the level where there is large uncertainty in estimating the variances.

The model for the inter-event standard error τ is given by:

$$\tau = \tau_1 + \frac{\tau_2 - \tau_1}{2} \times [\min\{\max(\mathbf{M}, 5), 7\} - 5] \quad (5.1)$$

The smoothed values of τ_1 and τ_2 are listed in Table 5.4. Magnitude-dependence in τ is much weaker than was estimated in the Sadigh et al. (1997) models and disappears for periods longer than 2 sec. The inter-event residuals also display increased variability near a spectral period of 0.1 sec compared to those for larger and smaller periods.

The intra-event residuals display stronger magnitude dependence than the inter-event residuals. The variability is also affected by the degree of nonlinearity in the soil, as defined by Equation (4.5). In addition, greater variability is observed in the residuals for sites with inferred values of V_{S30} than for sites with measured values of V_{S30} . The model for the intra-event standard deviation that incorporates these observations is give by:

$$\sigma = \left[\sigma_1 + \frac{\sigma_2 - \sigma_1}{2} (\min\{\max(\mathbf{M}, 5), 7\} - 5) + \sigma_4 \times AS \right] \times \sqrt{(\sigma_3 F_{Inferred} + 0.7 F_{Measured}) + (1 + NL)^2} \quad (5.2)$$

with

$$NL = \left(b \frac{y_{ref} e^\eta}{y_{ref} e^\eta + c} \right)$$

where $F_{Inferred}$ equals 1, if V_{S30} is inferred from geology, and 0 otherwise; $F_{Measured}$ equals 1, if V_{S30} is measured, and 0 otherwise; and AS equals 1 if the event is an aftershock, and 0 otherwise. Coefficients σ_1 , σ_2 , σ_3 , and σ_4 are listed in Table 5.4.

Table 5.4 Coefficients of variance model—Eqs. (5.1) and (5.2).

5.3 APPROXIMATE METHOD FOR CALCULATION OF TOTAL VARIANCE

The total variance for $\ln(y)$ is the sum of the inter-event and intra-event variances. Based on Equation (5.2), the intra-event variance σ^2 is a function of the random effect η such that the calculation of the total variance σ_T^2 requires integration over the random variable η . In the following we provide an approximate method that does not require integration. Taking the first two terms (first-order approximation) of the Taylor series expansion for σ_T^2 evaluated at $\eta = 0$ yields the expression:

$$\sigma_T^2 = (1 + NL_0)^2 \tau^2 + \sigma_{NL_0}^2$$

with

(5.3)

$$NL_0 = \left(b \frac{y_{ref}}{y_{ref} + c} \right)$$

In Equation (5.3), τ is obtained from Equation (5.1), and $\sigma_{NL_0}^2$ is evaluated using Equation (5.2) with $\eta = 0$. We compared the performance of Equation (5.3) to numerical integration over η and to Monte-Carlo simulation and found that it produces results that are, in most cases, within a few percent of the more exact calculations, with the values obtained from Equation (5.3) slightly larger than the more exact solutions. Therefore, we recommend the use of Equation (5.3) for calculating the total variance of $\ln(y)$ about the population mean evaluated by Equation (3.12a, 3.12b) with $\eta = 0$.

6 Model Results

6.1 INTER-EVENT RESIDUALS

Figure 6.1 shows the inter-event residuals, η_i , for main shocks. The residuals do not exhibit a trend with magnitude. The values for California and non-California earthquakes do not show any trends with respect to the population mean, indicating that both sets of earthquakes are consistent with the model. These results indicate that the data from the other active tectonic regions are consistent with ground motions from California earthquakes. The inter-event term for the Chi-Chi main shock is approximately $2\times\tau$ below the population mean for pga (0.01 sec spectral acceleration), and becomes positive for periods longer than 1.0 sec.

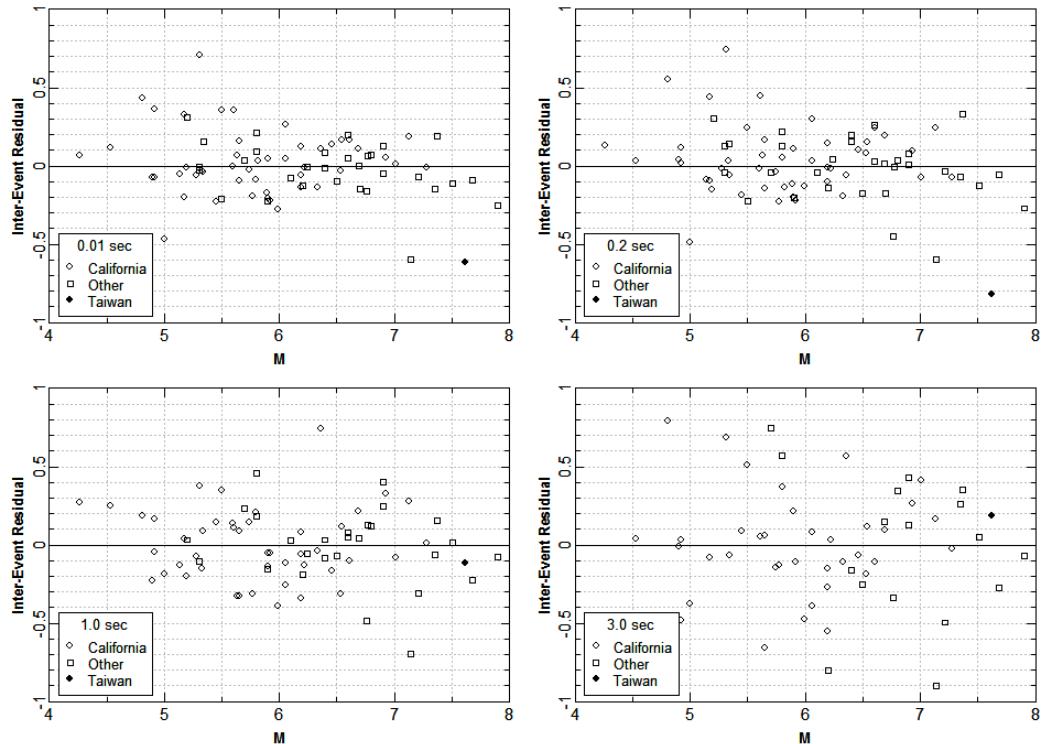

Fig. 6.1 Main shock inter-event residuals for spectral periods of 0.01 sec (pga), 0.2, 1.0, and 3.0 sec.

6.2 INTRA-EVENT RESIDUALS

Figures 6.2–6.5 show the intra-event residuals plotted versus \mathbf{M} , R_{RUP} , V_{S30} , and y_{ref} for spectral periods of 0.01 (pga), 0.2, 1.0 and 3.0 sec, respectively. The residuals do not exhibit any trends with respect to \mathbf{M} , R_{RUP} , V_{S30} , and y_{ref} . The site response model we have developed (Eq. 3.9) assumes that there is no deamplification of ground motions relative to y_{ref} for sites with V_{S30} greater than 1130 m/sec. Although there is very little data in the PEER-NGA database for such sites, the limited data, if anything, suggest a slight upward trend in the residuals. The site amplification model developed here does not account for the effect of the lower kappa expected for hard rock sites, which would lead to increases in high-frequency ground motions.

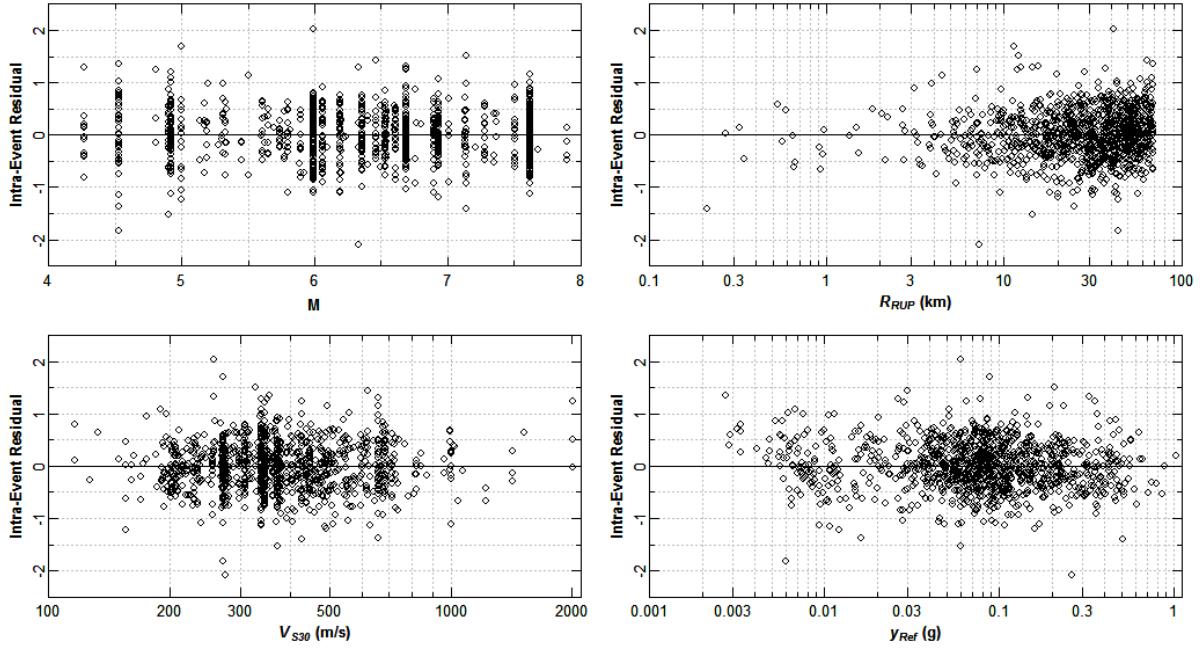

Fig. 6.2 Intra-event residuals for spectral period of 0.01 sec (pga) plotted against \mathbf{M} , R_{RUP} , V_{S30} , and y_{ref}

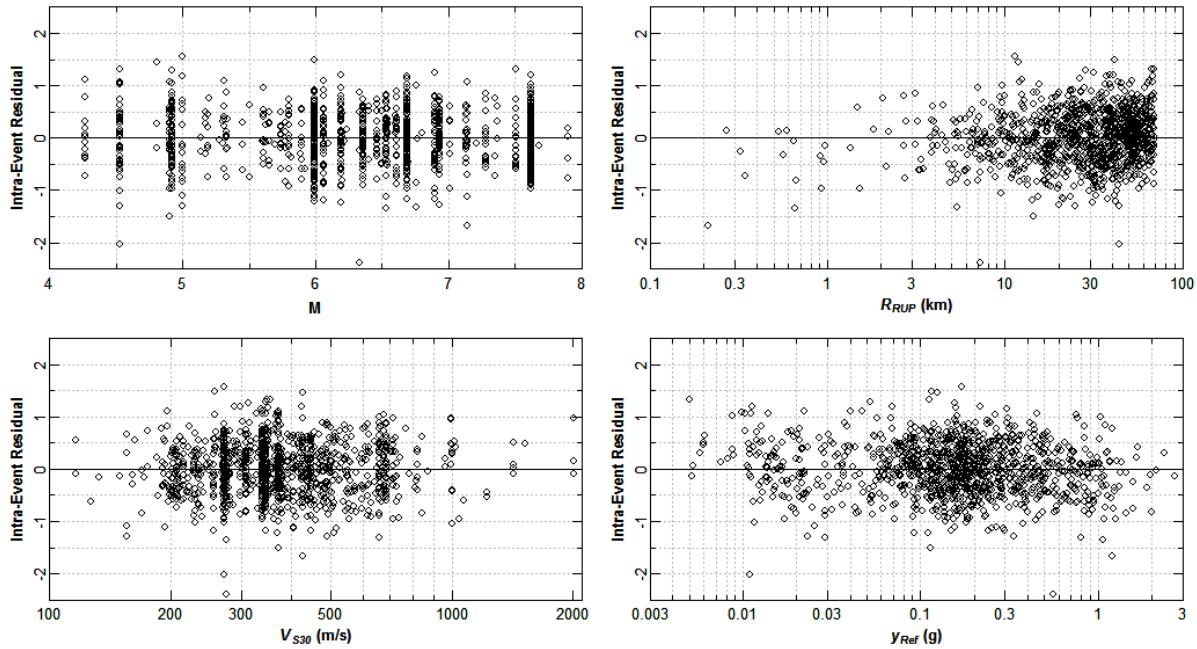

Fig. 6.3 Intra-event residuals for spectral period of 0.2 sec plotted against M , R_{RUP} , V_{S30} , and y_{ref}

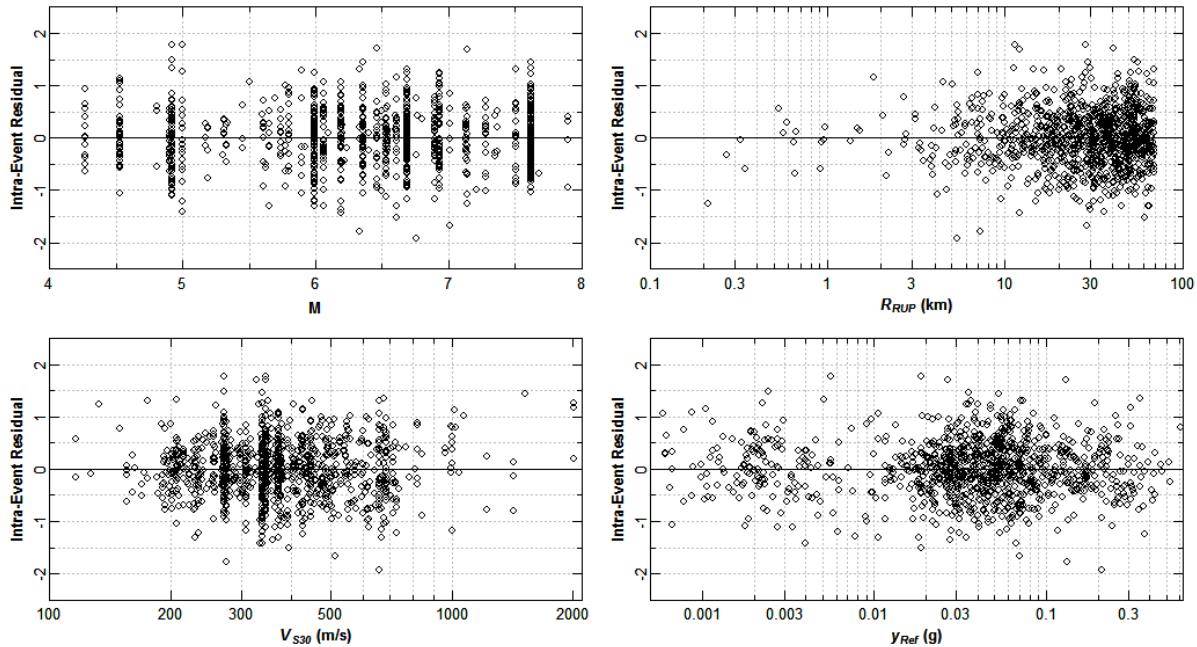

Fig. 6.4 Intra-event residuals for spectral period of 1.0 sec plotted against M , R_{RUP} , V_{S30} , and y_{ref}

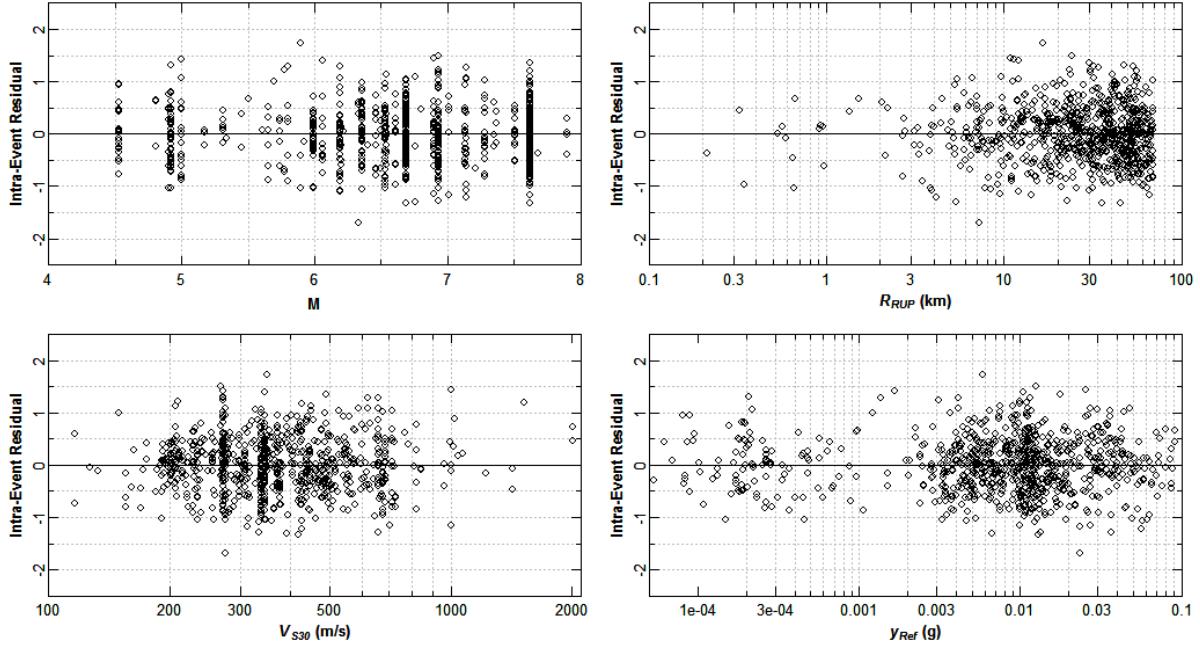

Fig. 6.5 Intra-event residuals for spectral period of 3.0 sec plotted against M , R_{RUP} , V_{S30} , and y_{ref}

Figure 6.6 shows intra-event residuals plotted against R_{RUP} for the 10 earthquakes in the NGA database for which we developed extended pga data sets. The intra-event residuals are computed using the inter-event term calculated from just the NGA data within 70 km as part of our overall fit to the NGA model. These results show that the model provides a good fit at distances greater than 70 km. Also shown is the bias in the NGA data set at larger distances.

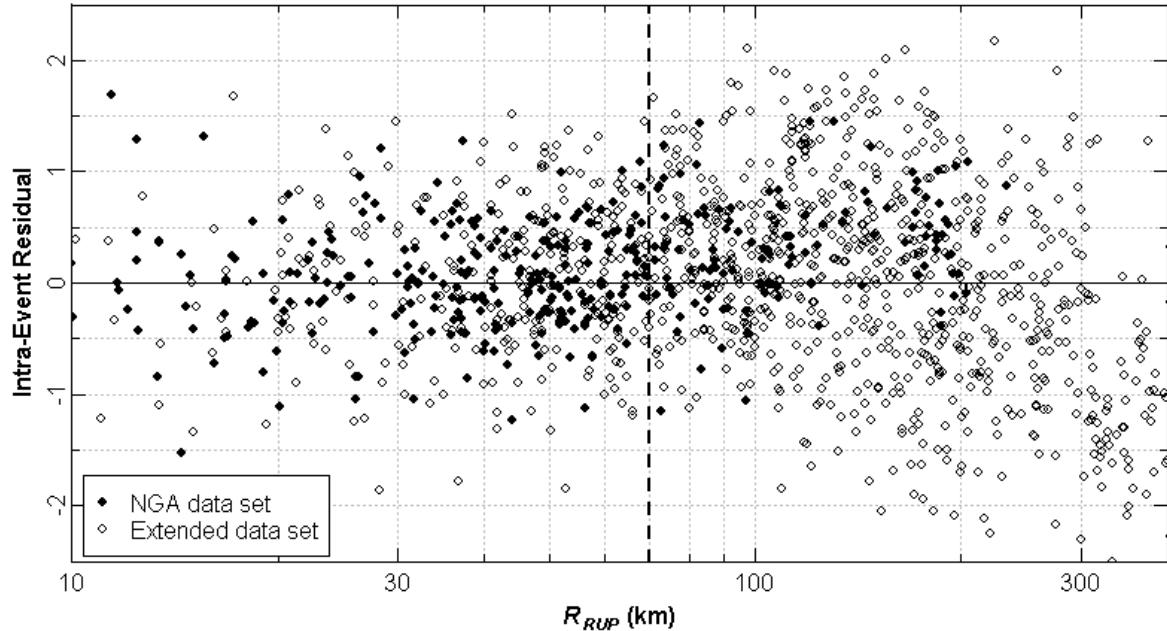

Fig. 6.6 Intra-event residuals for pga for the 1994 Northridge, 1998 San Juan Bautista, 1999 Hector Mines, 2000 Yountville, 2001 Mohawk Valley, 2001 Anza, 2002 Baja, 2002 Gilroy, 2002 Yorba Linda, and 2003 Big Bear City earthquakes.

6.3 COMPARISONS WITH DATA FOR INDIVIDUAL EARTHQUAKES

Appendix E contains plots showing the model fit to the data for individual earthquakes. The prediction curves in these plots are earthquake specific, meaning they include the inter-event random effect.

6.4 NONLINEAR SOIL AMPLIFICATION

Figure 6.7 compares the soil amplifications versus V_{S30} predicted by the nonlinear soil model developed as part of our ground motion model with the site amplifications computed by Silva (2008) using equivalent linear site response analyses and by Choi and Stewart (2003) using empirical ground motion data. The soil amplification model developed in this study compares well with the site response results computed by Silva (2008) for spectral periods of 0.01, 0.2, and 1.0 sec and shows greater amplification at the spectral period of 3.0 sec. Our model also compares well to Choi and Stewart's results at spectral periods of 0.01 and 1.0 sec, is more nonlinear at the spectral period of 0.2 sec, and shows greater amplification at the period of 3.0 sec.

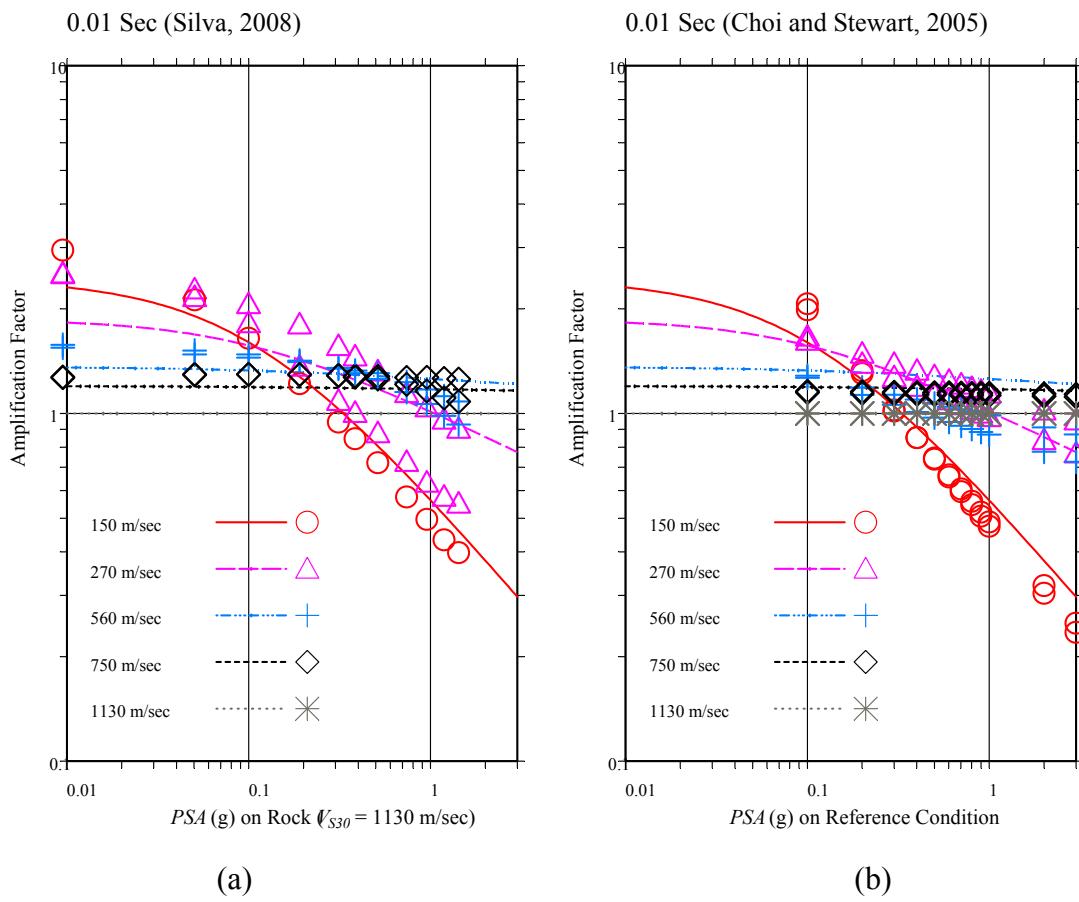

Fig. 6.7a Nonlinear soil amplification factor predicted by ground motion model developed in this study (lines) compared to those obtained by (a) Silva (2008) and (b) Choi and Stewart (symbols), for spectral period of 0.01 sec (pgs).

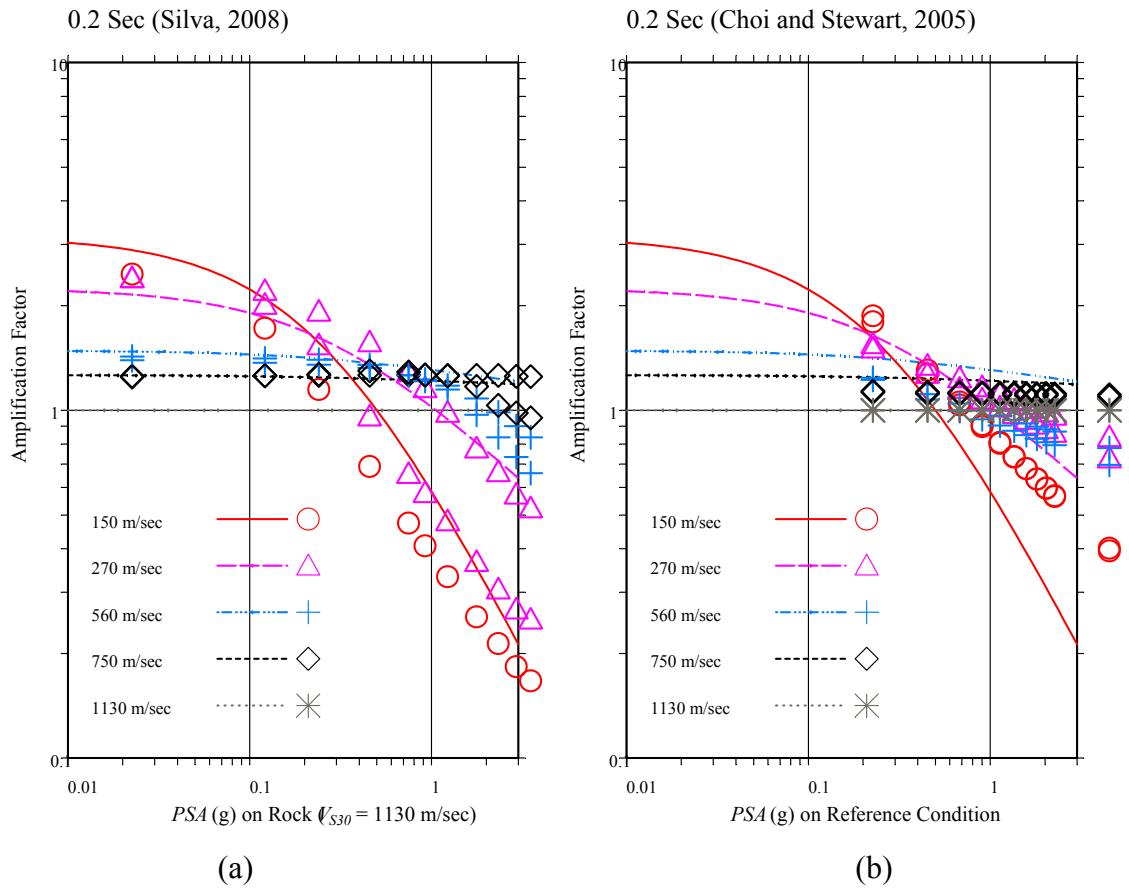

Fig. 6.7b Nonlinear soil amplification predicted by ground motion model developed in this study (lines) compared to those obtained by (a) Silva (2008) and (b) Choi and Stewart (symbols), for spectral period of 0.2 sec.

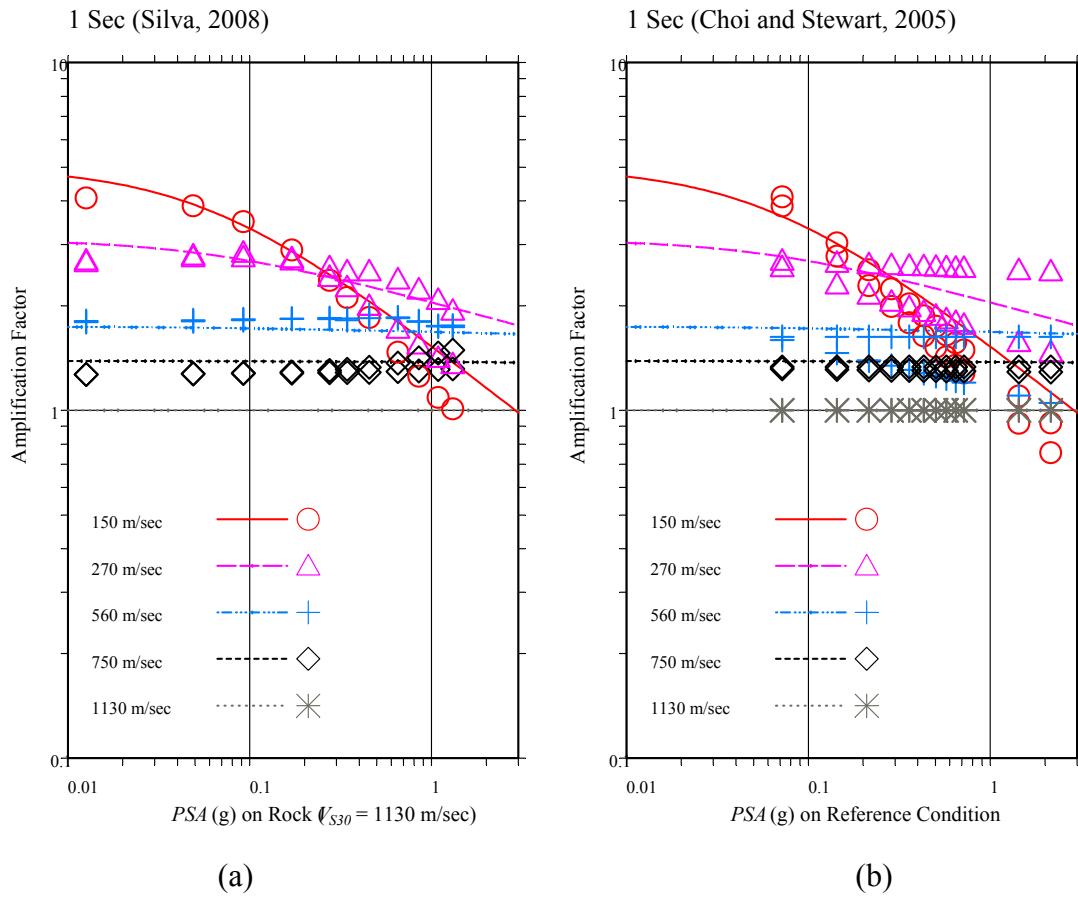

Fig. 6.7c Nonlinear soil amplification predicted by ground motion model developed in this study (lines) compared to those obtained by (a) Silva (2008) and (b) Choi and Stewart, for spectral period of 1.0 sec.

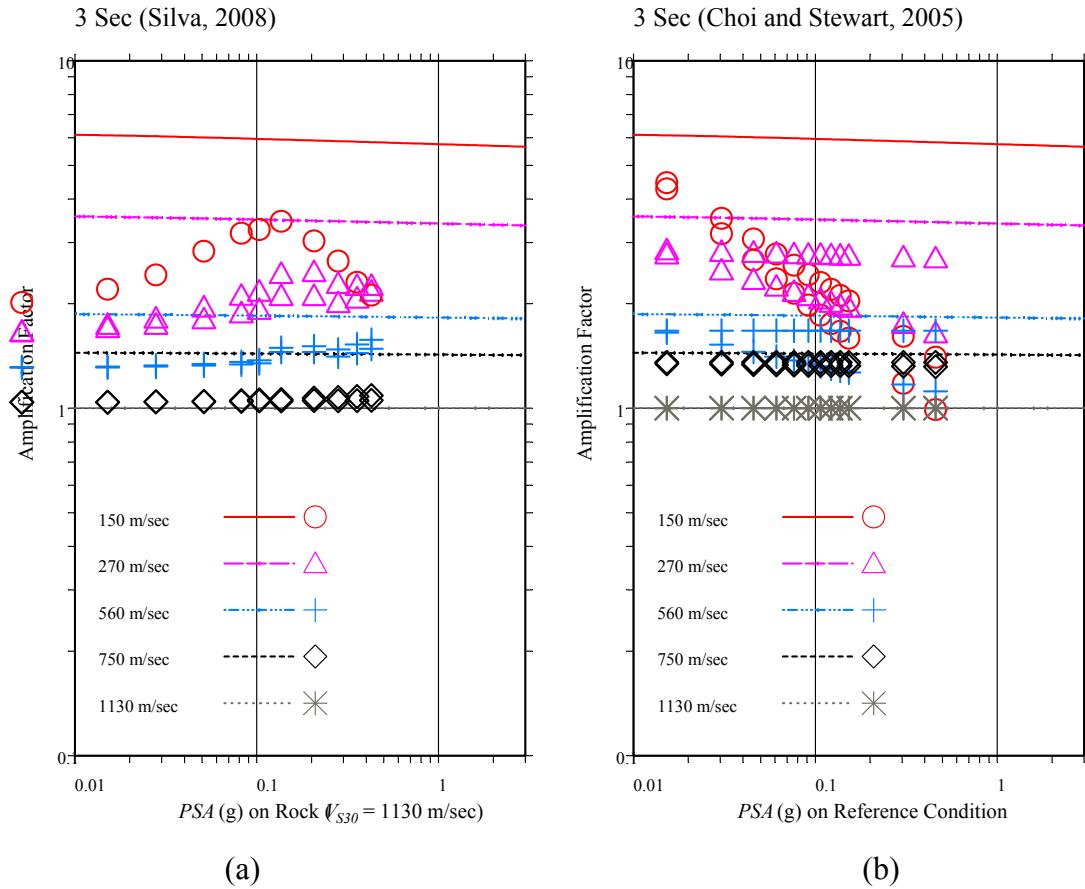

Fig. 6.7d Nonlinear soil amplification predicted by ground motion model developed in this study (lines) compared to those obtained by (a) Silva (2008) and (b) Choi and Stewart (symbols), for spectral period of 3.0 sec.

6.5 COMPARISON WITH PREVIOUS MODEL

Figures 6.8–6.10 compare magnitude and distance scaling produced by the new model with that predicted by the models developed by Sadigh et al. (1997). The comparisons require an assessment of V_{S30} representative of the Sadigh et al. (1997) relationships. For soil, we have used a value of 310 m/s, the velocity suggested by Boore et al. (1997) as representative of generic soil. This value is also approximately the geometric mean of V_{S30} for sites in the PEER-NGA database that would have been included in the Sadigh et al. (1997) soil database (see also Appendix F). For generic rock, Boore et al. (1997) suggested a value of 620 m/s. However, we think that this may be higher than the average for the data used by Sadigh et al. (1997), which included recordings from many sites that are now classified as NEHRP C, and have used a V_{S30} of 520 m/s for the comparisons.

The bulk of the ground motion data are for soil sites and at distances between 20 and 50 km and the two models produce generally similar results for these conditions and short-period motions. The models are more similar for soil than for rock, which is to be expected given that the majority of ground motion data is recorded on soil sites. The difference between the two models increases for longer period motions, with the new model generally indicating lower motions. This difference is attributed largely to the much larger spectral acceleration database available to constrain the model coefficients compared to the amount of data available for use by the Sadigh et al. (1997). This claim is also supported by the findings of Appendix F. Differences in the model formulations account for the differences in predicted ground motions at the edges of the data. The distance scaling formulations are quite different, resulting in differences in the shape of the attenuation curves beyond 70 km, especially for long-period motions. The introduction of the hanging-wall effect results in increases in the model predictions over those of Sadigh et al. (1997) for sites located in the hanging wall and reductions at other sites. The style of faulting effect for reverse earthquakes is now smaller and reduces with increasing spectral period. Differences in the predictions also occur for smaller magnitudes at close distances due to the revised scaling formulations.

Figures 6.11–6.12 compare median response spectra for the two models. The spectral shapes generated by the two models are similar, but as indicated in Figures 6.8–6.10, the updated model produces lower long-period motions.

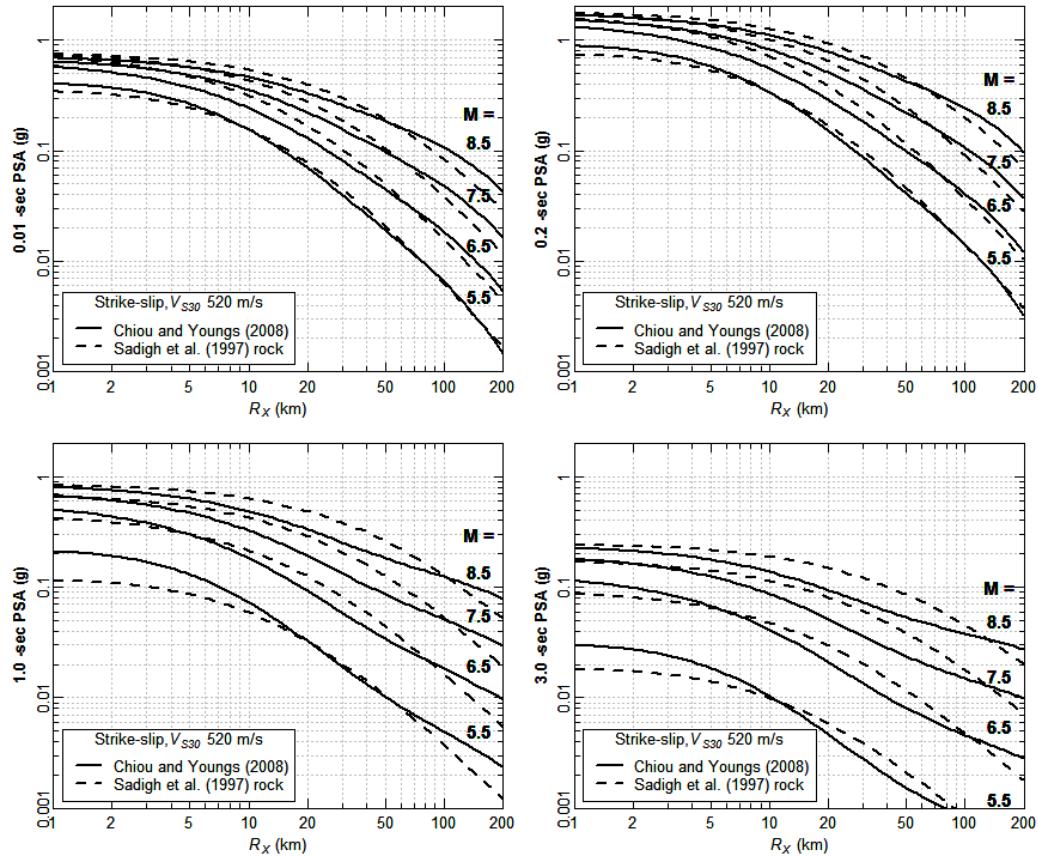

Fig. 6.8 Magnitude and distance scaling predicted by the model developed in this study and predicted by Sadigh et al. (1997) for horizontal distance from a vertical strike-slip fault and soft rock sites ($V_{S30} = 520$ m/s).

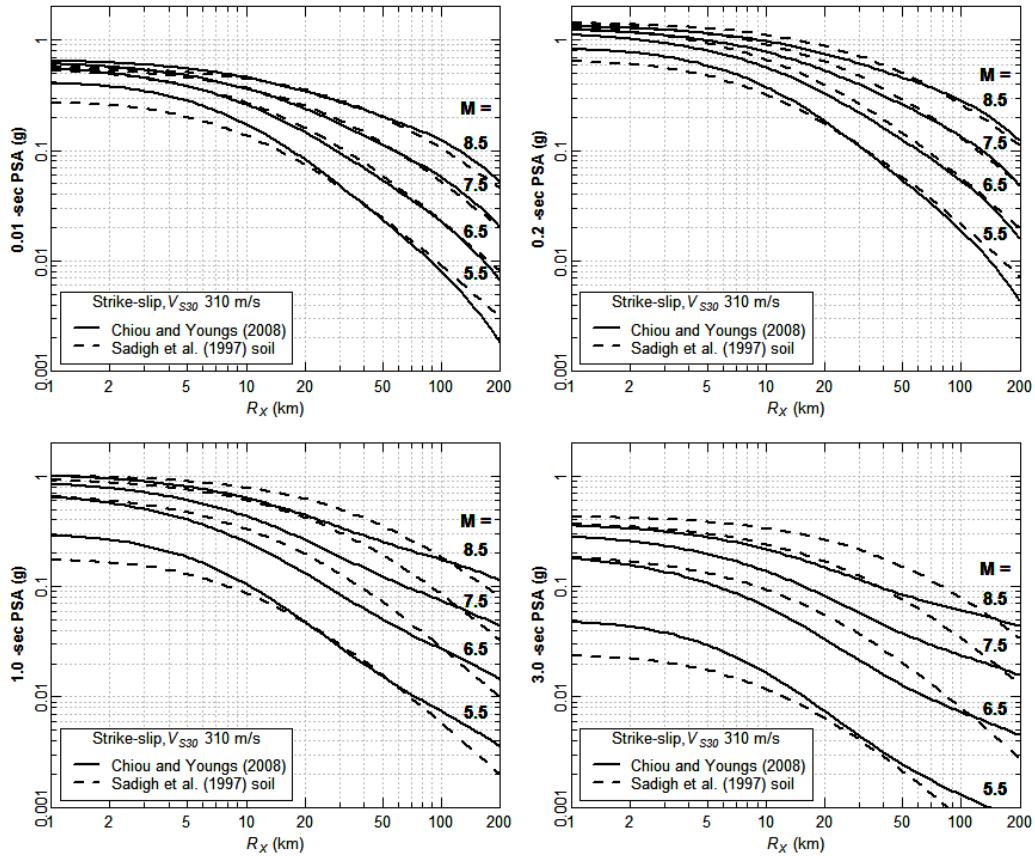

Fig. 6.9 Magnitude and distance scaling predicted by the model developed in this study and predicted by Sadigh et al. (1997) for horizontal distance from a vertical strike-slip fault and firm soil sites ($V_{S30} = 310 \text{ m/s}$).

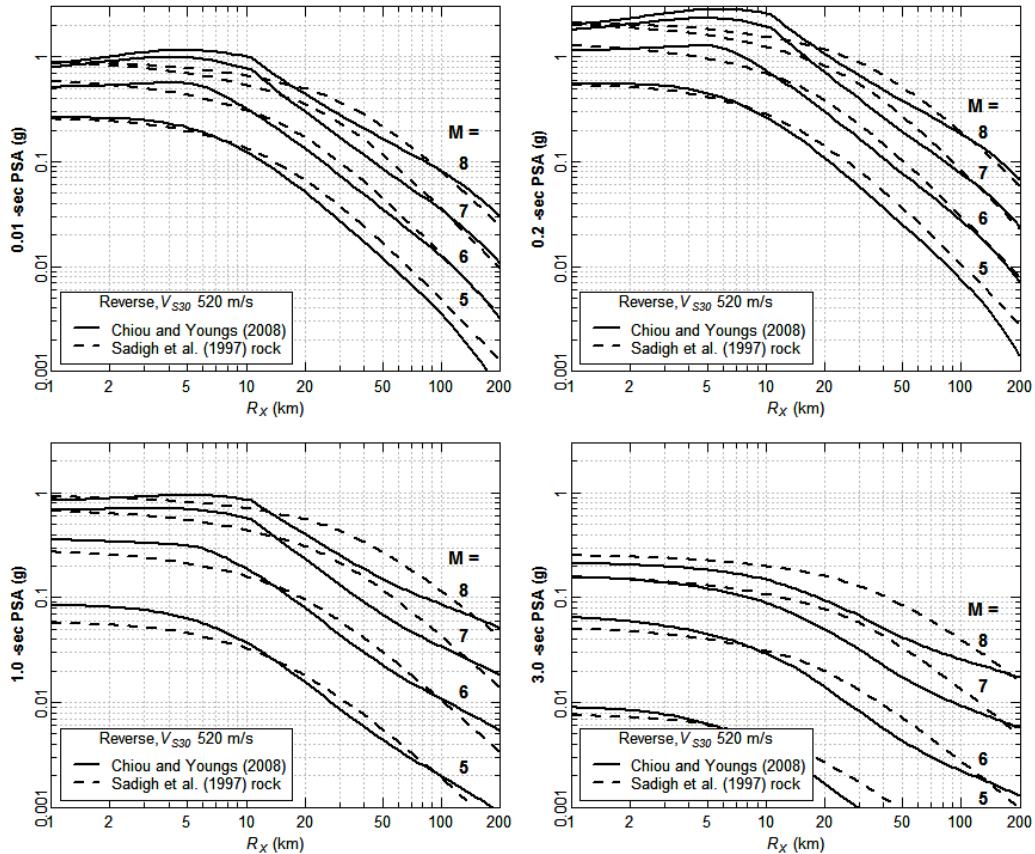

Fig. 6.10 Magnitude and distance scaling predicted by the model developed in this study and predicted by Sadigh et al. (1997) for horizontal distance from top edge of rupture on a reverse fault ($\delta = 45^\circ$) and soft rock sites ($V_{S30} = 520$ m/s).

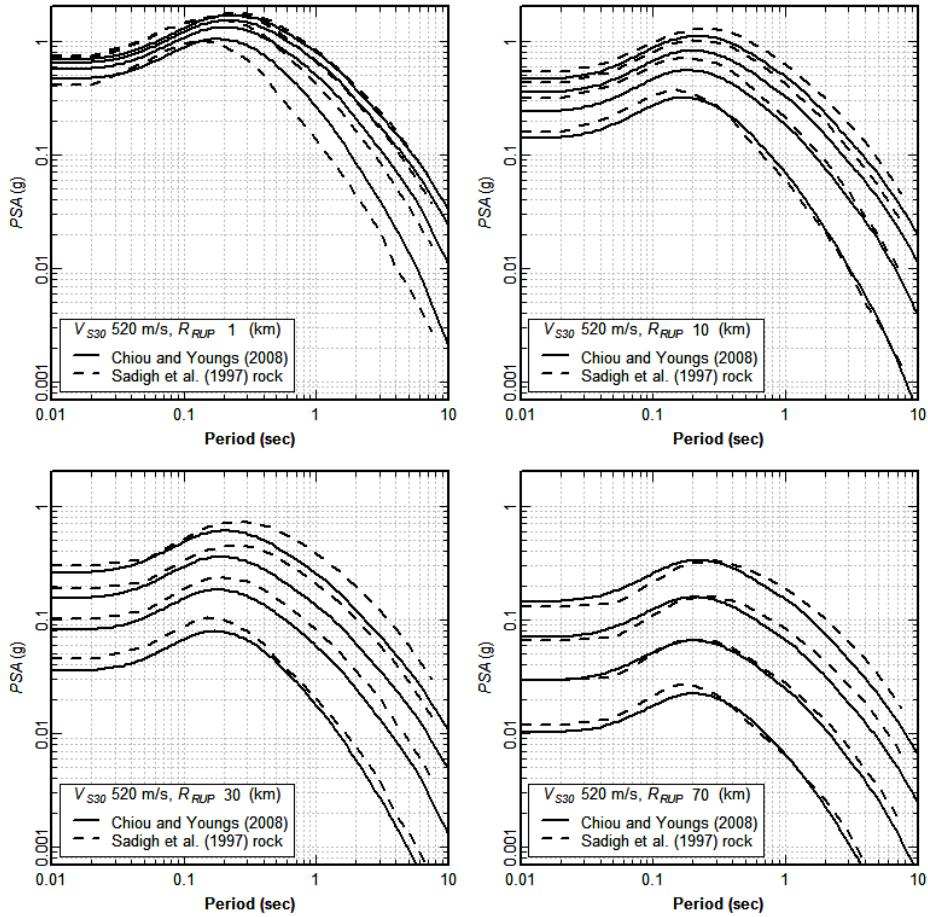

Fig. 6.11 Median response spectra predicted by the model developed in this study and predicted by Sadigh et al. (1997) for strike-slip earthquakes and soft rock sites ($V_{S30} = 520$ m/s). Magnitudes are in order of increasing amplitude M 5.5, 6.5, 7.5, and 8.5.

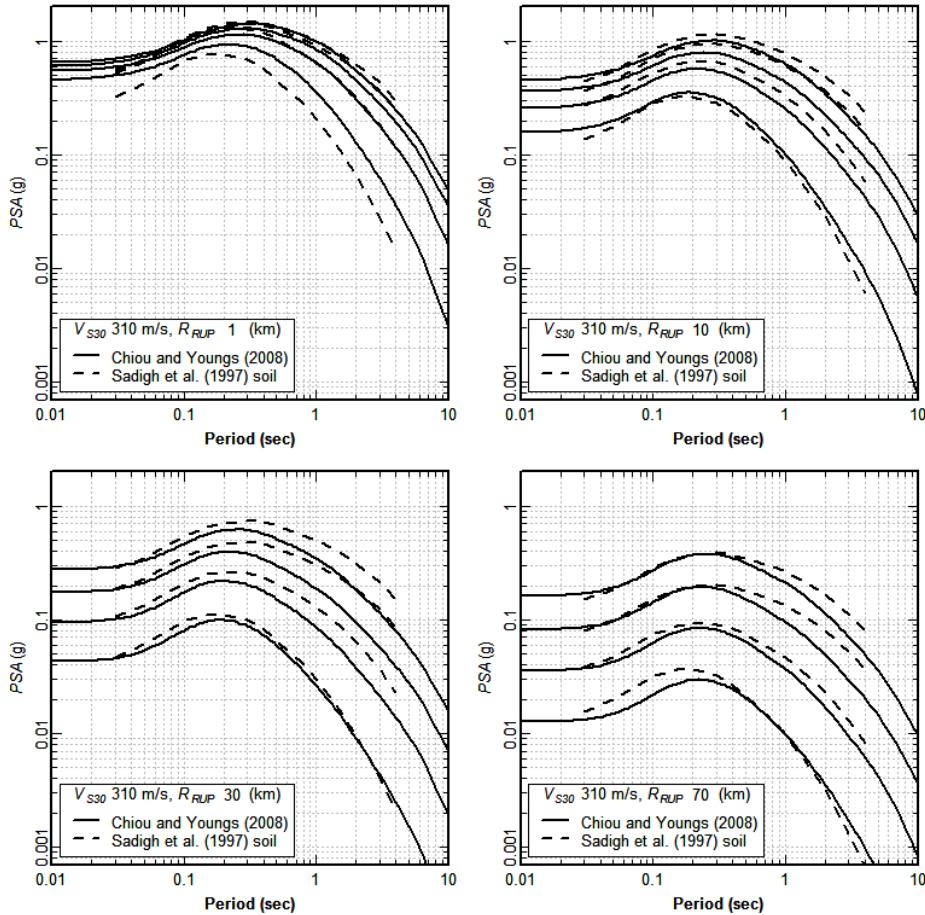

Fig. 6.12 Median response spectra predicted by the model developed in this study and predicted by Sadigh et al. (1997) for strike-slip earthquakes and firm soil sites ($V_{S30} = 310 \text{ m/s}$). Magnitudes are in order of increasing amplitude M 5.5, 6.5, 7.5, and 8.5.

Figure 6.13(a) compares the total standard errors for the updated model with linear soil response compared to those for the Sadigh et al. (1997) models. The total standard errors for **M 5** earthquakes are similar but the updated standard errors for **M 7** earthquakes are larger. Figure 6.13(b) shows the effect of soil nonlinearity on the total standard errors of *pga*.

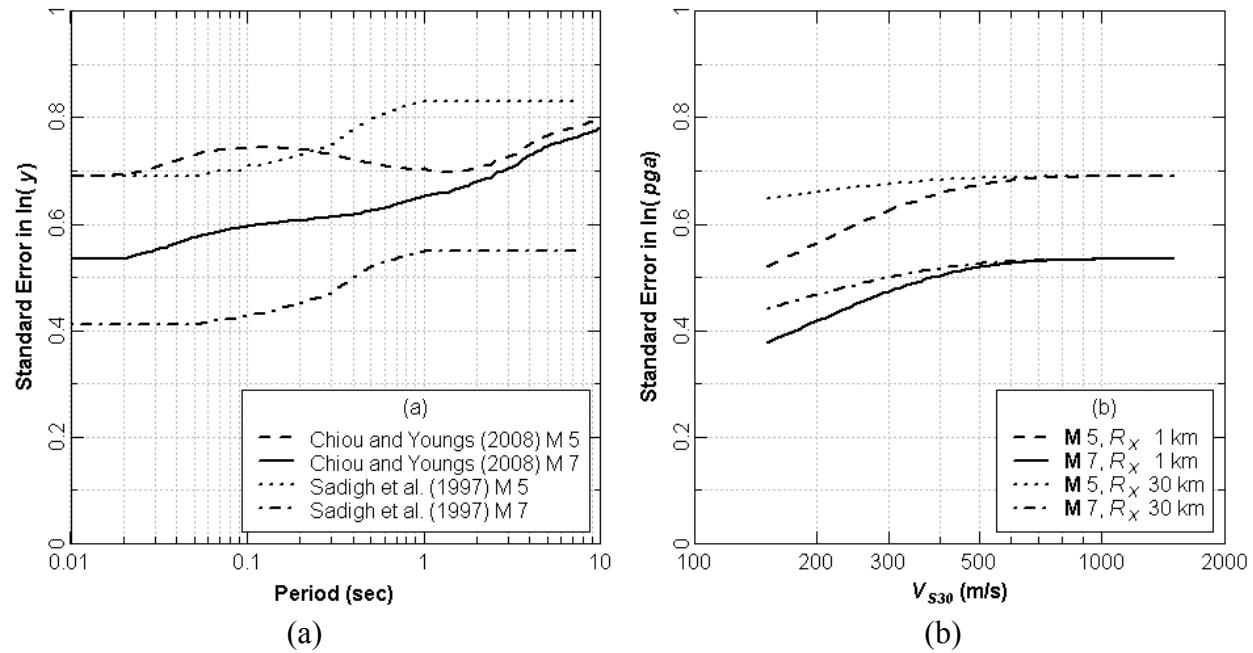

Fig. 6.13 (a) Total standard errors for the model with linear soil response developed in this study and Sadigh et al. (1997). (b) Effect of soil nonlinearity on pga total standard error for the model developed in this study.

7 Example Calculations

FORTRAN routine CY2008.FOR (http://peer.berkeley.edu/products/Chiou_Youngs_NGA.html) is provided to implement the model developed in this study. Example input and output files are provided for four scenarios: **M 5** and **M 7** strike-slip earthquakes and **M 5** and **M 7** reverse-faulting earthquakes. The required input variables are indicated by the header record in the example input files. The routine accepts its main input and writes the output to the console. After invoking at the command prompt, the routine loops over prompts for the input and output files.

Table 7.1 list the computed median spectral accelerations (y) for the four example scenarios for spectral periods of 0.01, 0.2, 1.0, 3.0 sec. The total standard deviation (σ_{total}) is computed by the approximate method of Equation (5.3) for the case of $F_{Inferred} = 0$ (i.e., measured V_{S30}).

8 Model Applicability

The model developed in this study is considered to be applicable for estimating pseudo-spectral accelerations (5% damping) and peak motions for earthquakes in active tectonic regions in which the following conditions apply:

- $4 \leq M \leq 8.5$ for strike-slip earthquakes
- $4 \leq M \leq 8.0$ for reverse and normal faulting earthquakes
- $0 \leq R_{RUP} \leq 200$ km
- $150 \text{ m/sec} \leq V_{S30} \leq 1500 \text{ m/sec}$

The model was developed using the anelastic attenuation coefficient γ constrained by data from California earthquakes. For application in other regions where earthquakes at distances greater than about 50 km are a major contributor to the hazard, adjustments to the $\gamma(M)$ coefficients $c_{\gamma 1}$ and $c_{\gamma 2}$ may be warranted. These adjustments can be made using the hybrid approach developed by Campbell (2003). In making such adjustments, we stress the need for the user to obtain estimates of Q for the two regions that are based on consistent geometric spreading models.

The site response portion of the ground motion model was constrained such that all ground motion amplification factors are 1 for V_{S30} greater than 1130 m/s. As the rock velocity increases we expect shallow crustal damping (i.e., “kappa”) to decrease, resulting in increases in high-frequency motion. Data for such sites are not present in the PEER-NGA database in sufficient quantity to estimate this effect, and it is not captured in our model. Such effects should be considered if the model is to be applied to sites with V_{S30} greater than 1500 m/sec.

The model was developed using recordings from earthquakes with a maximum depth to top of rupture of 15 km and a maximum hypocentral depth of 19 km. The model predicts a linear increase in $\ln(\gamma_{ref})$ with increasing Z_{TOR} over this depth range for most spectral periods.

Application of the model in regions with very thick crust (e.g., $>> 20$ km) is an extrapolation outside of the range of data used to develop the model coefficients.

The ground motion model presented here is sensitive to the value of sediment depth, $Z_{1.0}$, for the site. We have used data from the SCEC-3D Version 4 model for southern California and users should use this version to estimate values of $Z_{1.0}$ at sites in southern California. For general application, we recommend that the user estimate $Z_{1.0}$ from Equation (2.1) unless there is site-specific data to provide a better estimate (e.g., a site velocity profile). Note also that large values of $Z_{1.0}$ may produce numerical overflow of the cosh function in some compilers and the user may need to determine the appropriate limits in implementing our model in computer programs.

Appendix B: Estimation of Distance and Geometry Measures for Earthquakes without Finite Rupture Models

B.1 APPROACH

There are 110 earthquakes in the NGA data set that do not have finite fault models, and therefore have only epicentral and hypocentral distances listed in the flat file. Rupture distances and source-site geometry parameters were estimated for the recordings from these earthquakes by simulating 101 possible rupture planes for each earthquake, computing the distance measures for each site for each simulation, and then taking the median of these values for use in completing the metadata in the PEER-NGA database. The estimated parameters include R_{RUP} , R_{JB} , R_{SEIS} , R_{RMS} , the source-site angle θ_{SITE} , the hanging-wall and footwall indicators F_{HW} and F_{FW} , and the fault rupture width W and depth to top of rupture, Z_{TOR} .

B.2 SIMULATION PROCESS

The first step was to simulate the fault rupture dimensions. The rupture area, A , was simulated using the Wells and Coppersmith (1994) relationship for all fault types:

$$\log(A) = -3.49 + 0.91M, \quad \sigma_{\log(Area)} = 0.24 \quad (\text{B.1})$$

Figure B.1 shows the data for rupture area versus M for the finite rupture models in the PEER-NGA database. The black lines show a linear fit to the data (solid = mean, dashed = 90% confidence on mean). The blue line, from Wells and Coppersmith (1994), falls within the 90% confidence interval and provides a closer fit to the data for smaller-magnitude earthquakes of

primary interest in the simulation, as those earthquakes without finite fault models are principally of magnitude < **M** 6.

The aspect ratio of the rupture was then simulated using the relationship:

$$\log(AR) = (0.01752 - 0.00472F_{NM} - 0.01099F_{RV}) * (\mathbf{M} - 4)^{3.097} \quad \sigma_{\log(AR)} = 0.16 \quad (\text{B.2})$$

where F_{NM} and F_{RV} are (0,1) dummy variables for normal and reverse earthquakes, respectively. This relationship was defined by fitting the aspect ratio data for the PEER-NGA finite fault model data set (Fig. B.2). Correlation in the residuals between rupture area and aspect ratio was low (<0.3), and it was assumed that they were independent in the simulation.

Using the simulated values of A and AR , the rupture width W and rupture length L were computed assuming a rectangular fault rupture.

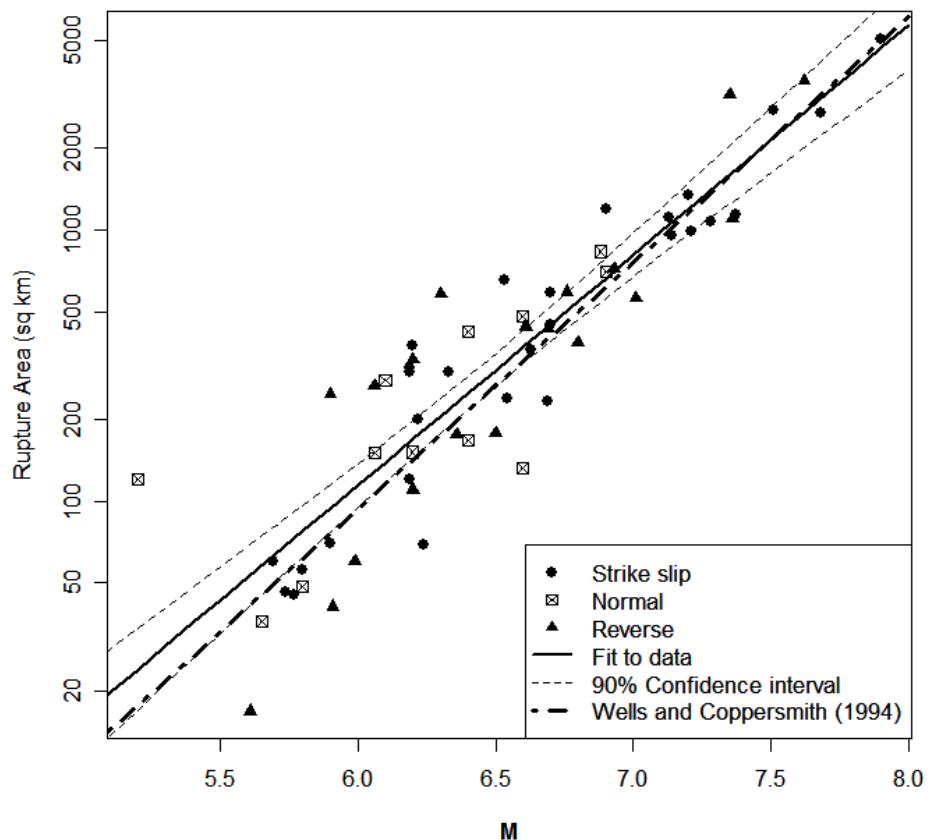

Fig. B.1 Data for **M** versus rupture area from PEER-NGA finite fault model dataset. Lines show fit to data and Wells and Coppersmith (1994) relationship for all slip types.

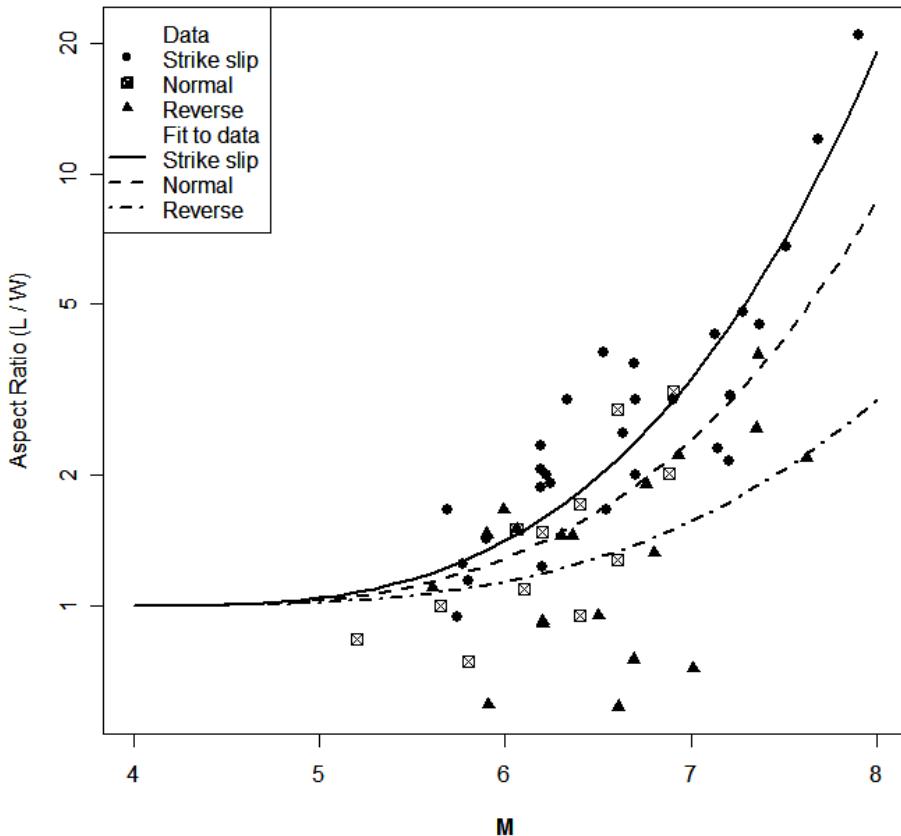

Fig. B.2 Data for M versus aspect ratio from PEER-NGA finite fault model dataset.

The next step was to locate the rupture plane in space. The vertical location of the simulated rupture with respect to the hypocenter was simulated using empirical distributions for the hypocenter location derived from the PEER-NGA set of rupture models. The observed and smoothed empirical distributions are shown in Figure B.3. If the top of the simulated rupture plane extended above 0 depth, it was placed at 0 depth. The rupture plane dip was fixed at the value assigned to the earthquake.

The location of the hypocenter along strike was simulated using data from Mai et al. (2005) for earthquakes $\leq M 6.5$. This distribution is shown in Figure B.4.

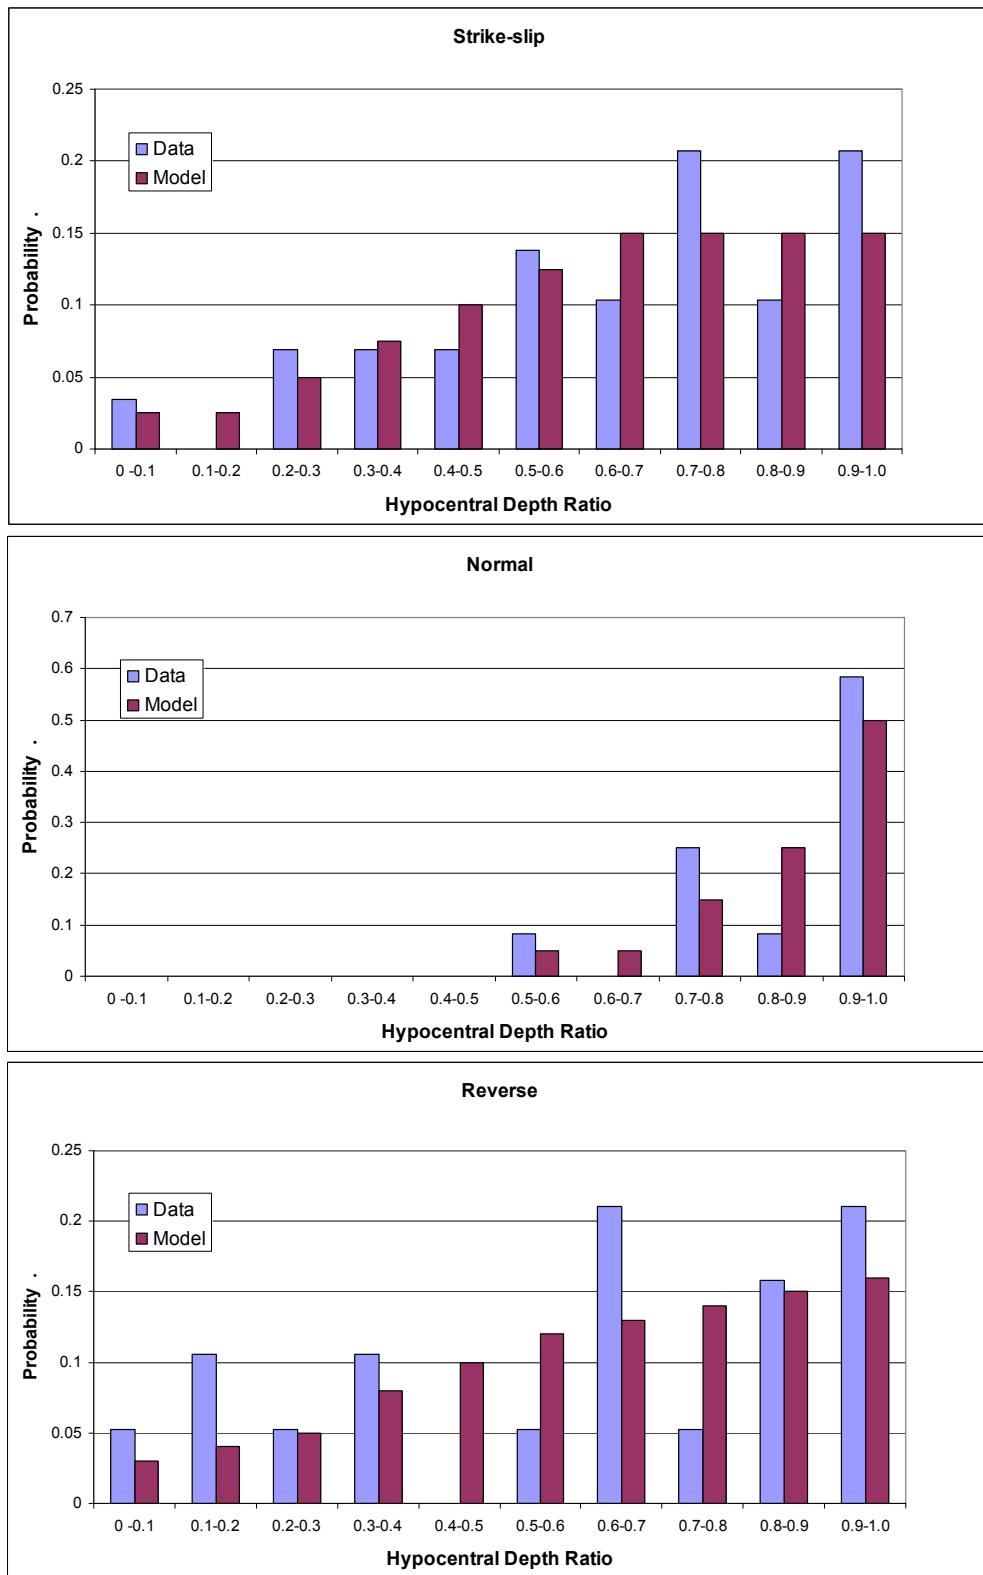

Fig. B.3 Empirical distributions for vertical location of hypocenter in rupture plane derived from the PEER-NGA rupture model data set (“Data”) and smoothed for use in simulations (“Model”).

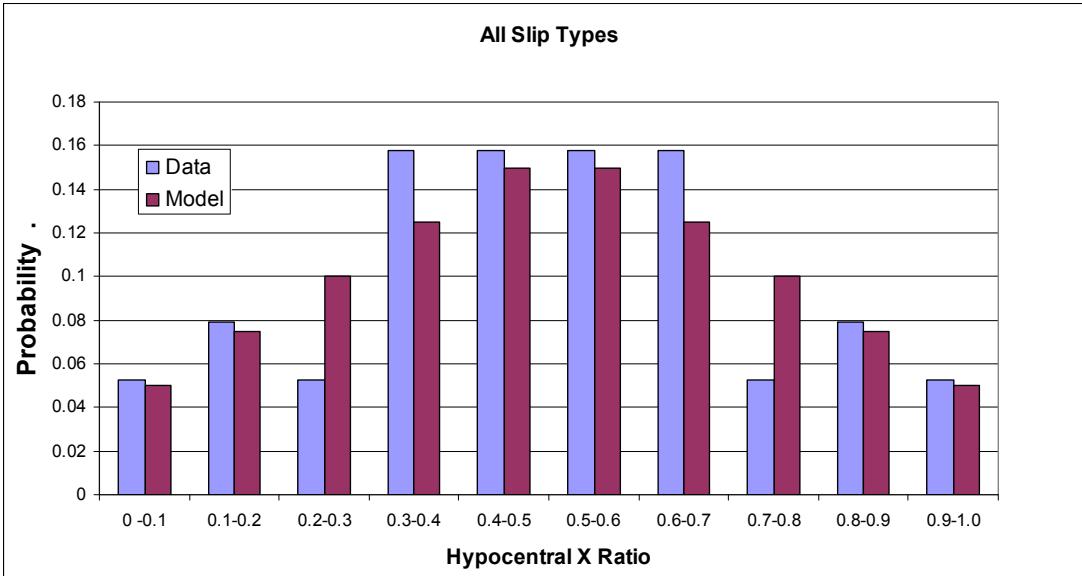

Fig. B.4 Distributions for horizontal location of hypocenter in rupture plane derived from data for $M \leq 6.5$ earthquakes presented in Mai et al. (2005) (“Data”) and smoothed for use in simulations (“Model”).

For each simulated rupture plane, the distance to all sites was computed in terms of R_{JB} , R_{SEIS} (assuming a minimum seismogenic depth of 3 km), R_{RMS} distance, and closest distance to rupture, R_{RUP} . The depth to top of rupture, Z_{TOR} and the source-site angle were also computed.

The values selected for use were the median values for each site from the 101 simulations. The median was chosen because most of the values enter regressions as logs.

Figure 2.3 in the main text shows the ratio of the estimated values of the Joyner-Boore distance to the epicentral distance and the ratio of the estimated rupture distance to hypocentral distance for the 702 sites associated with the 110 earthquakes analyzed.

Ken Campbell provided the distances he obtained for the 1992 Big Bear M 6.46 earthquake based on a rupture model he developed for that event. Figure B.5 compares his estimates of R_{JB} and R_{RUP} to those obtained from this exercise. The values are close, indicating that the process provides reasonable estimates of rupture distance measures.

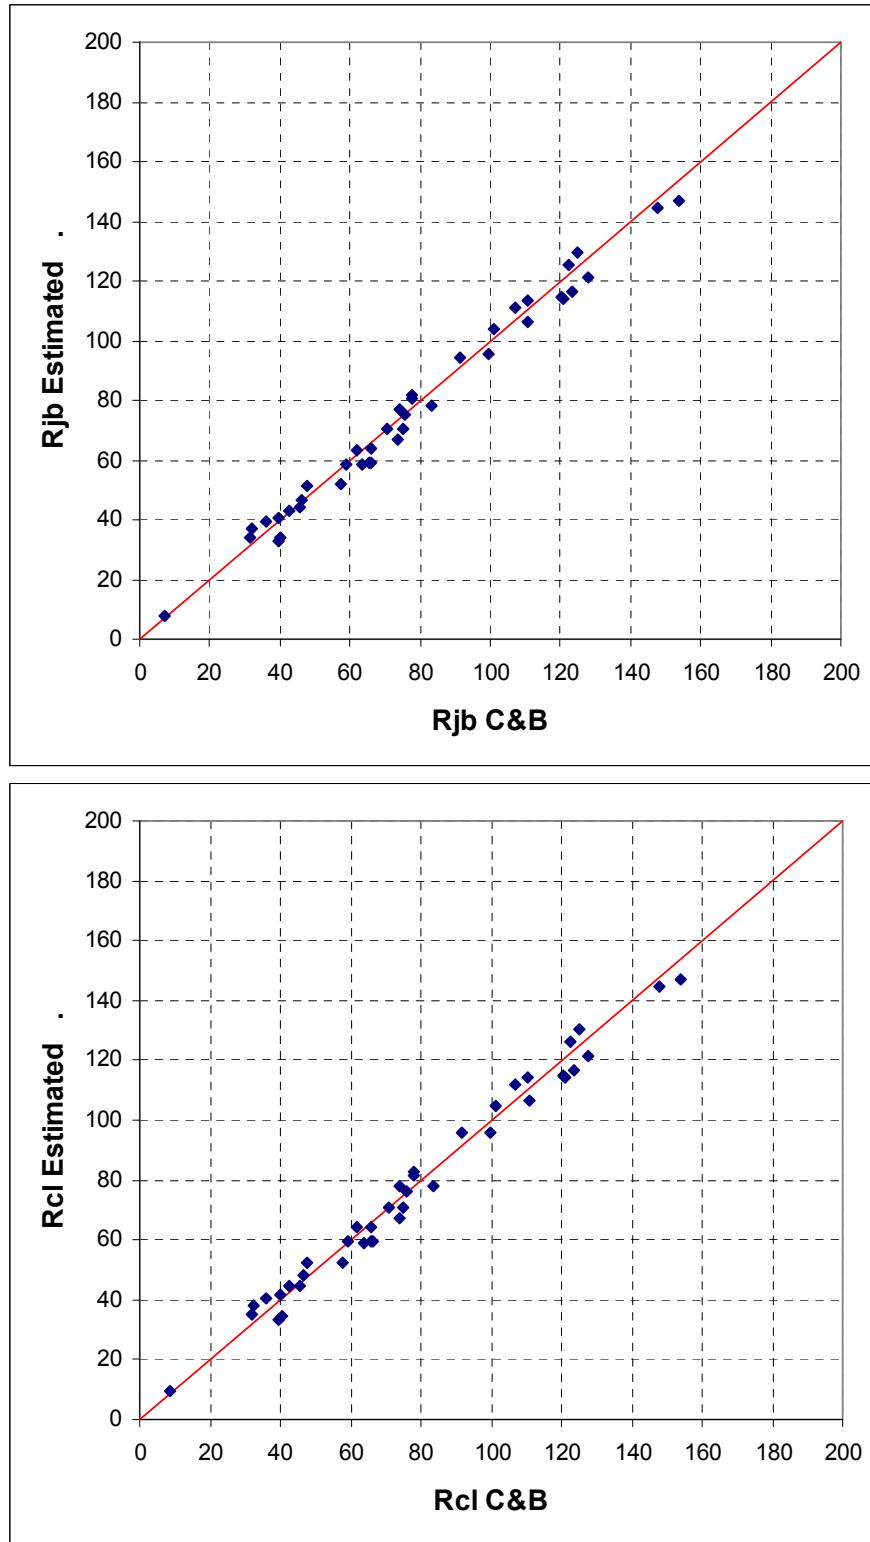

Fig. B.5 Comparison of estimated Joyner-Boore distances (R_{JB}) closest distance to rupture (R_{RUP}) obtained in this analysis to those obtained by Ken Campbell and used in Campbell and Bozorgnia (2003).

Appendix C: Estimation of V_{S30} at CWB's Free-Field Sites

Brian Chiou and K.L. Wen²
(June 08, 2006)

C.1 INTRODUCTION

When a site's V_{S30} measurement is missing, it is typically estimated using an empirical relationship between V_{S30} and other site information, such as surface geology or Geomatrix's 3rd letter (C_3). This approach has been used by the PEER-NGA project and has also been widely used in California (Wills and Silva 1998; Wills and others 2000; Wills and Clahan 2004) and other regions. This short note reports our efforts to establish an empirical V_{S30} - C_3 relationship for CWB's strong-motion sites in Taiwan. The Taiwan-specific relationship uses C_3 as the main predictor. It also uses station elevation to capture the within-category variation of V_{S30} . Using elevation as a V_{S30} predictor leads to a significant improvement of mapping accuracy within a site category, particularly for Geomatrix's category D.

C.2 DATA

V_{S30} data used in this study were derived from the *P-S* logging information provided by NCREE, who has been conducting site investigation of strong-motion stations in Taiwan³. During the period of 2000–2004 a total of 231 holes were drilled and logged. The site investigation project is still on going and more *P-S* logging data will become available in the next several years.

For each drill hole, Dr. Walt Silva (PE&A) reviewed the *P-S* logging data, smoothed the velocity profile, and computed V_{S30} from the smoothed profile. We used the resulting V_{S30} at 165

² Professor, Department of Geophysics, National Central University, Taiwan.

³ Plots of the drilling logs are available on CWB's website (<http://www.cwb.gov.tw/>).

sites for our study. The other 66 strong-motion sites were not used because either the drill hole is less than 20 m deep or a Geomatrix C₃ classification has not been assigned yet.

Other collected site data are: (1) Geomatrix's 2nd and 3rd letters (D. Wells, pers. comm., 2004); (2) The site classification (PSC) by Lee et al. (2001); and (3) Station elevation (Lee et al. 2001).

C.3 VARIATION OF V_{S30} WITHIN A SITE CATEGORY

Histogram of the 165 V_{S30} data, grouped by C₃, is shown in Figure C.1. This figure illustrates two challenges in using Geomatrix's C₃ to map V_{S30} in Taiwan. First, categories A, B, and C are not distinguishable as far as V_{S30} is concerned. Second, the most populous category (D) is bimodal. It has been suggested that, due to the active tectonic in Taiwan, the higher the elevation the stiffer the surface material tends to be (Lee et al. 2001). To explore if elevation could be used to explain the V_{S30} variation, V_{S30} data are plotted as a function of station elevation in Figure C.2. Except for a few outliers, a strong correlation of V_{S30} with the station elevation is clearly seen, particularly for the Geomatrix-D category. The bimodal distribution observed in Figure C.1 can be adequately modeled by the station elevation.

C.4 MAPPING V_{S30} BY C₃ AND ELEVATION

Based on the trends noted in Figure C.2, the following functional form is used to model V_{S30} as a function of station elevation (Elv , in meters),

$$\ln(V_{S30}) = \ln(\phi_1) + \frac{\ln(\phi_2) - \ln(\phi_1)}{1 + e^{(\ln(\phi_3) - \ln(Elv)) / \phi_4}}.$$

Interpretations of the model coefficients are as follows: ϕ_1 and ϕ_2 are the asymptotic V_{S30} as the elevation approaches 0 and ∞ , respectively; at the elevation of ϕ_3 meters, V_{S30} is the (geometric) average of the two asymptotes.

The above functional form was used to fit V_{S30} data for each of the five Geomatrix categories. The resulting coefficients (ϕ_i , $i=1, 4$) are listed in Table C.1 and the fitted curves are shown in the left hand plot of Figure C.3.

To illustrate the difference in inferred V_{S30} due to different mapping schemes, V_{S30} estimates for the non-measurement CWB sites are plotted in the right panel of Figure C.3. The solid lines represent estimated V_{S30} using the new model for Taiwan; circles are V_{S30} estimated using California's model (Silva 2004; see Note #34 in the site file NGA_Site_V017.XLS). Difference in estimated V_{S30} is not large, with the exception of Geomatrix-D category at elevation higher than 70m, which is expected.

Appendix D: ShakeMap Data

D.1 DATASET

The ground motion dataset described in this appendix was compiled from the southern California ShakeMap system by Boatwright and his colleagues at USGS (per. communication). It includes pga (in units of %g) and pgv (in units of cm/sec) from 252 earthquakes (Fig. D.1). Because only the larger of the two horizontal components is provided, we divide the listed pga value by 1.1 to adjust the value down to the expected level of average horizontal component. Epicenter location, focal depth, and local magnitude M_L of each earthquake are obtained from the SCSN (Southern California Seismic Network) earthquake catalog. Moment magnitude (M) is based on the moment from the SCSN moment tensor solution catalog.

Since most earthquakes are without a finite source model, rupture distance is imputed using the same procedure as described in Appendix B. For site conditions, we used the V_{S30} value in the NGA database or estimated it using the correlation between V_{S30} and surface geological unit as was used in NGA project. Surface geological unit at the station coordinates is provided by Chris Wills using the recently refined CGS site-conditions map (Wills et al. 2006). For stations without a geological unit and a NGA V_{S30} value, we used the site category (C) given in the USGS data file to infer V_{S30} (Wills et al. 2001):

$$C=1: V_{S30} = 674 \text{ (m/sec)}$$

$$C=2: V_{S30} = 423 \text{ (m/sec)}$$

$$C=3: V_{S30} = 281 \text{ (m/sec)}$$

$$C=4: V_{S30} = 165 \text{ (m/sec)}.$$

$Z_{1.0}$ is estimated from the V_{S30} value using equation (2.1) of the main text.

D.2 DATA SELECTION

We did not include any earthquake whose epicenter is outside or near the network boundary of the southern California ShakeMap system. The quality of pga data degrades as distance increases. A full quality control is not feasible; instead we removed pga from beyond the cutoff distance of $130 \times (\mathbf{M} - 2)$ km. Our cutoff distance is slightly more generous than the cutoff distance of $100 \times (\mathbf{M} - 2)$ km recommended by Boatwright et al. (2003) for northern California earthquakes. To get a reliable estimate of event term, we removed earthquakes with less than 20 data points. We also removed data that are obviously in errors. The final data subset includes 9060 pga data points from 102 earthquakes, ranging in magnitude from 3.39 to 5.17., pga values are in the range of 0.0007–24.5% g.

D.3 COMPARISON TO CHIOU AND YOUNGS (2008)

Plots of pga vs. distance are presented in Figure D.2 for each of the selected earthquakes. A similar comparison has been made using the preliminary model published in Chiou and Youngs (2006). Dashed line in each plot represents the population median prediction by Chiou and Youngs (2008) and the solid line represents the event-specific median (population median times e^η , η is the event term). Both predictions are evaluated from the mean V_{S30} of the recording stations. The event term of an earthquake is computed as the mean residual of data from that earthquake.

Figure D.3 shows all the event terms as a function of earthquake magnitude. A significant trend with magnitude is noted, suggesting that the magnitude scaling in Chiou and Youngs (2008) does not apply to earthquakes smaller than $\mathbf{M} 4.5$. To improve the misfits, coefficients c_3 and c_M of Chiou and Youngs (2008) must be revised. Since such revision will not affect the predictions of ground motion for large magnitude, we leave this revision to a future study.

Appendix E: Individual Earthquake Fits for Chiou and Youngs's (2008) Ground Motion Model

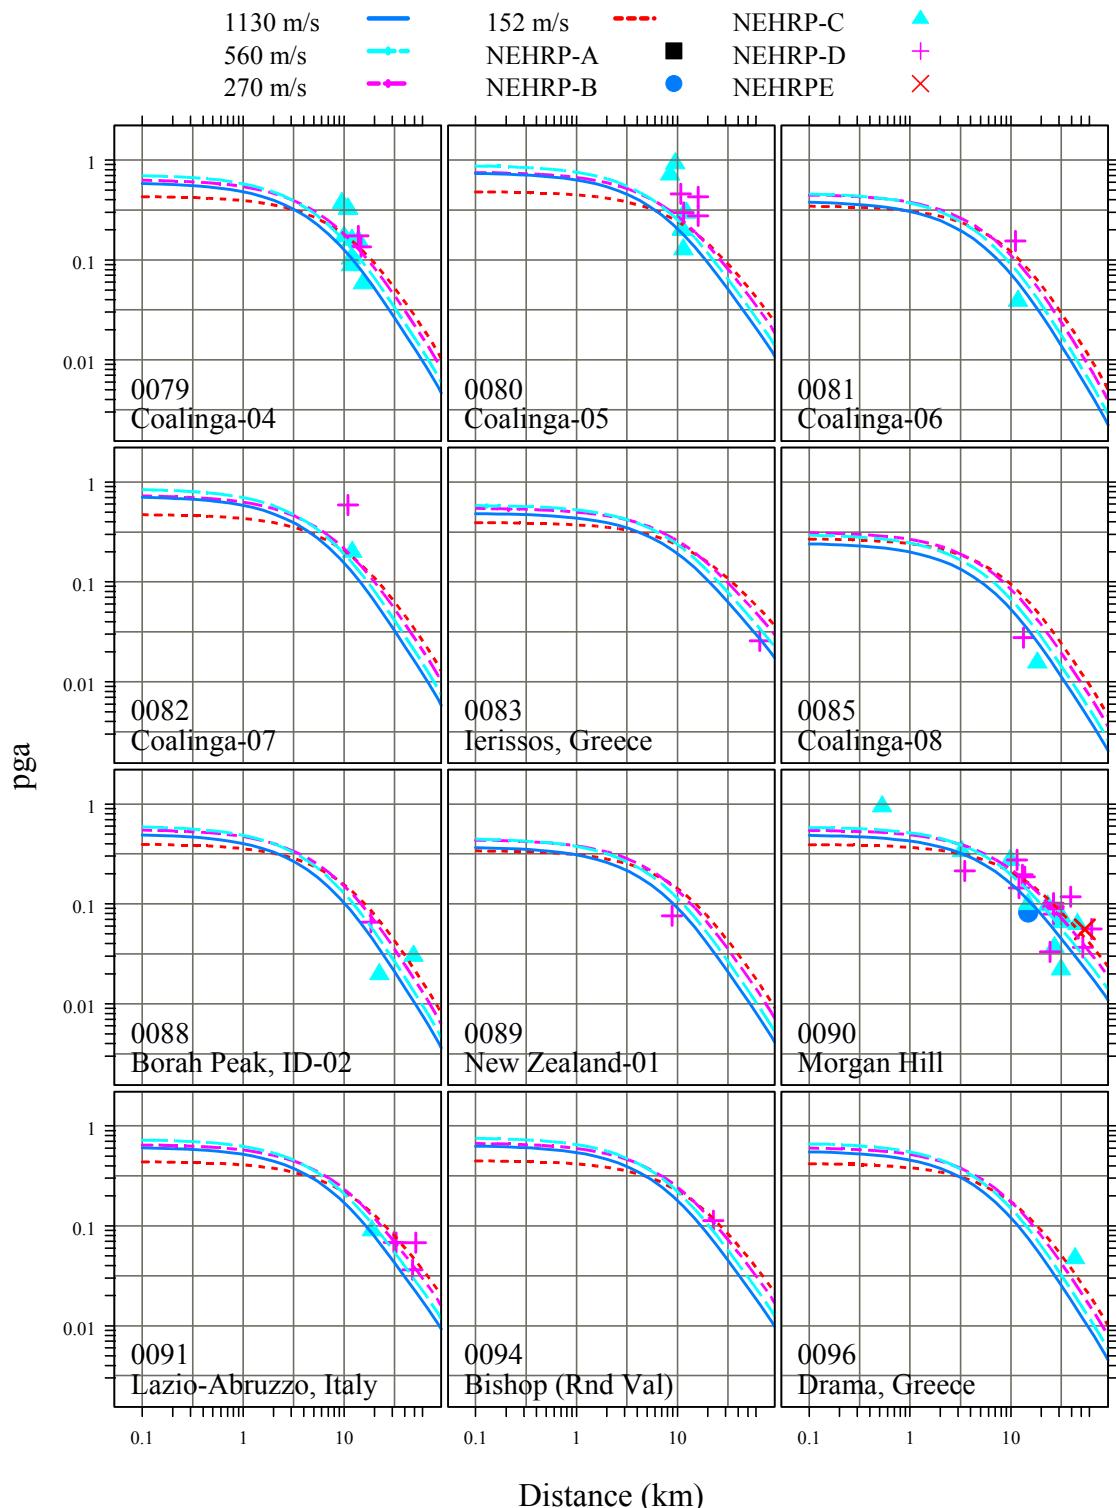

Plots in this appendix show the fits of Chiou and Youngs's (2008) model to empirical data for each earthquake used in the regressions analysis. Predictions are evaluated without hanging-wall effect. The predicted curves are color coded to indicate the V_{S30} values used in making the ground motion prediction, and the ground motion data are color coded by the recording site's NEHRP site class. The results are shown for the ground motion parameters of pseudo spectral acceleration at spectral periods of 0.01 (pga), 0.2, 1.0, and 3.0 sec.

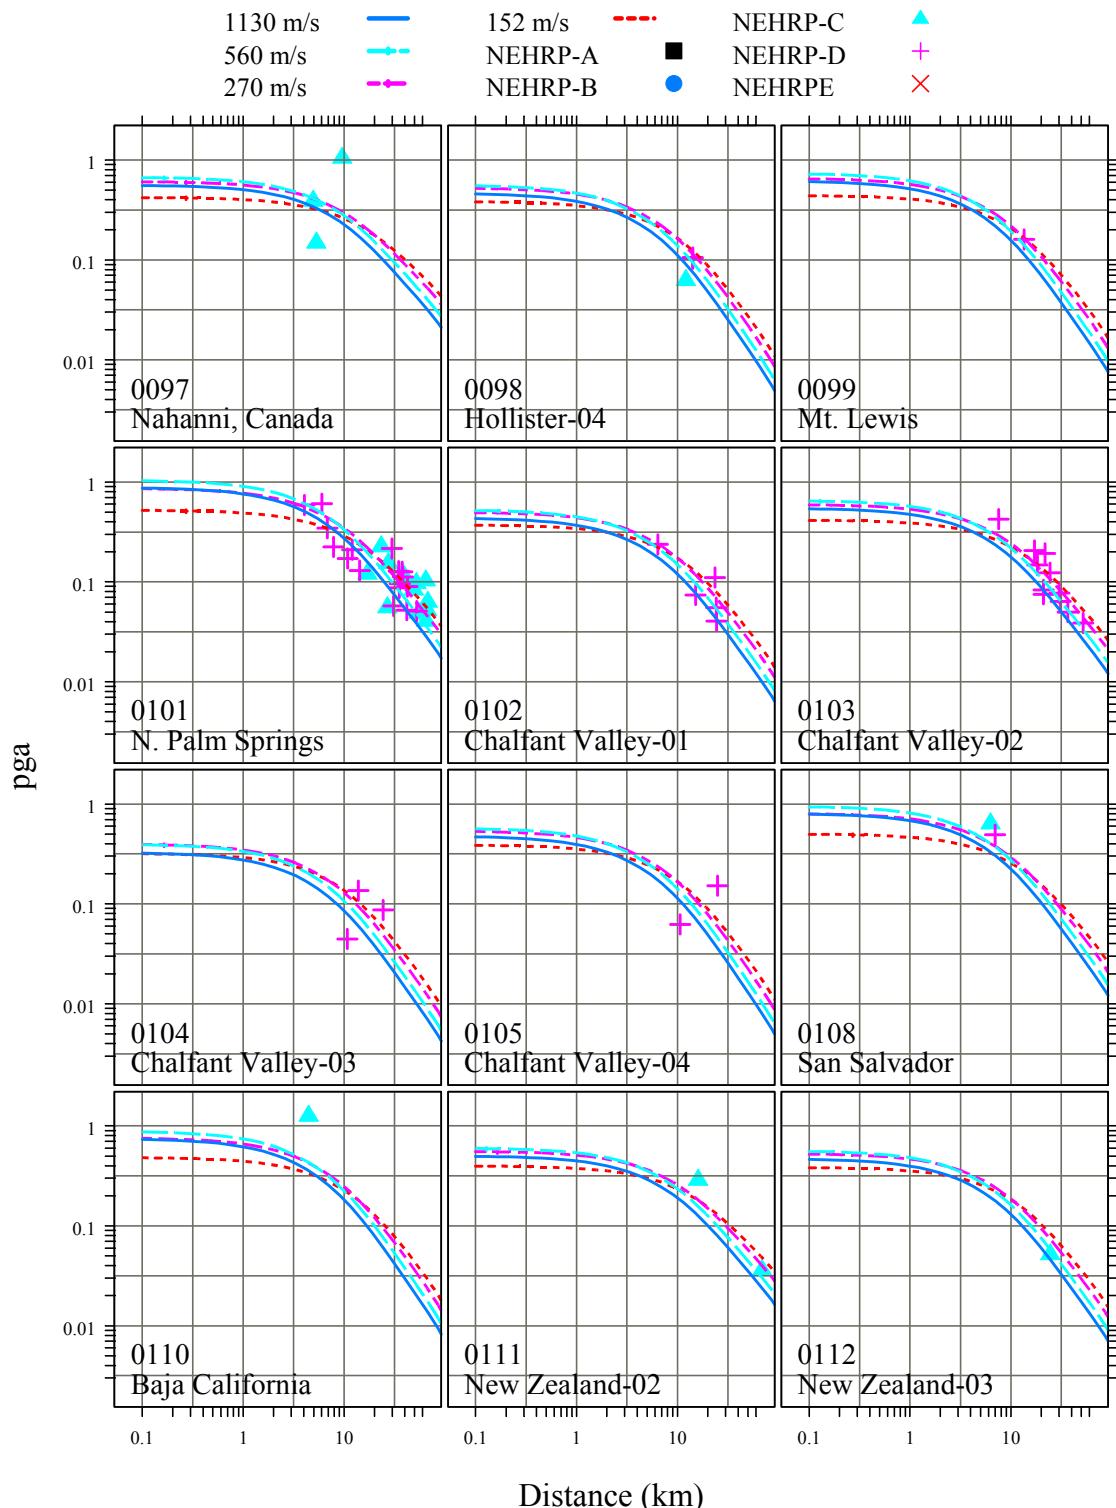

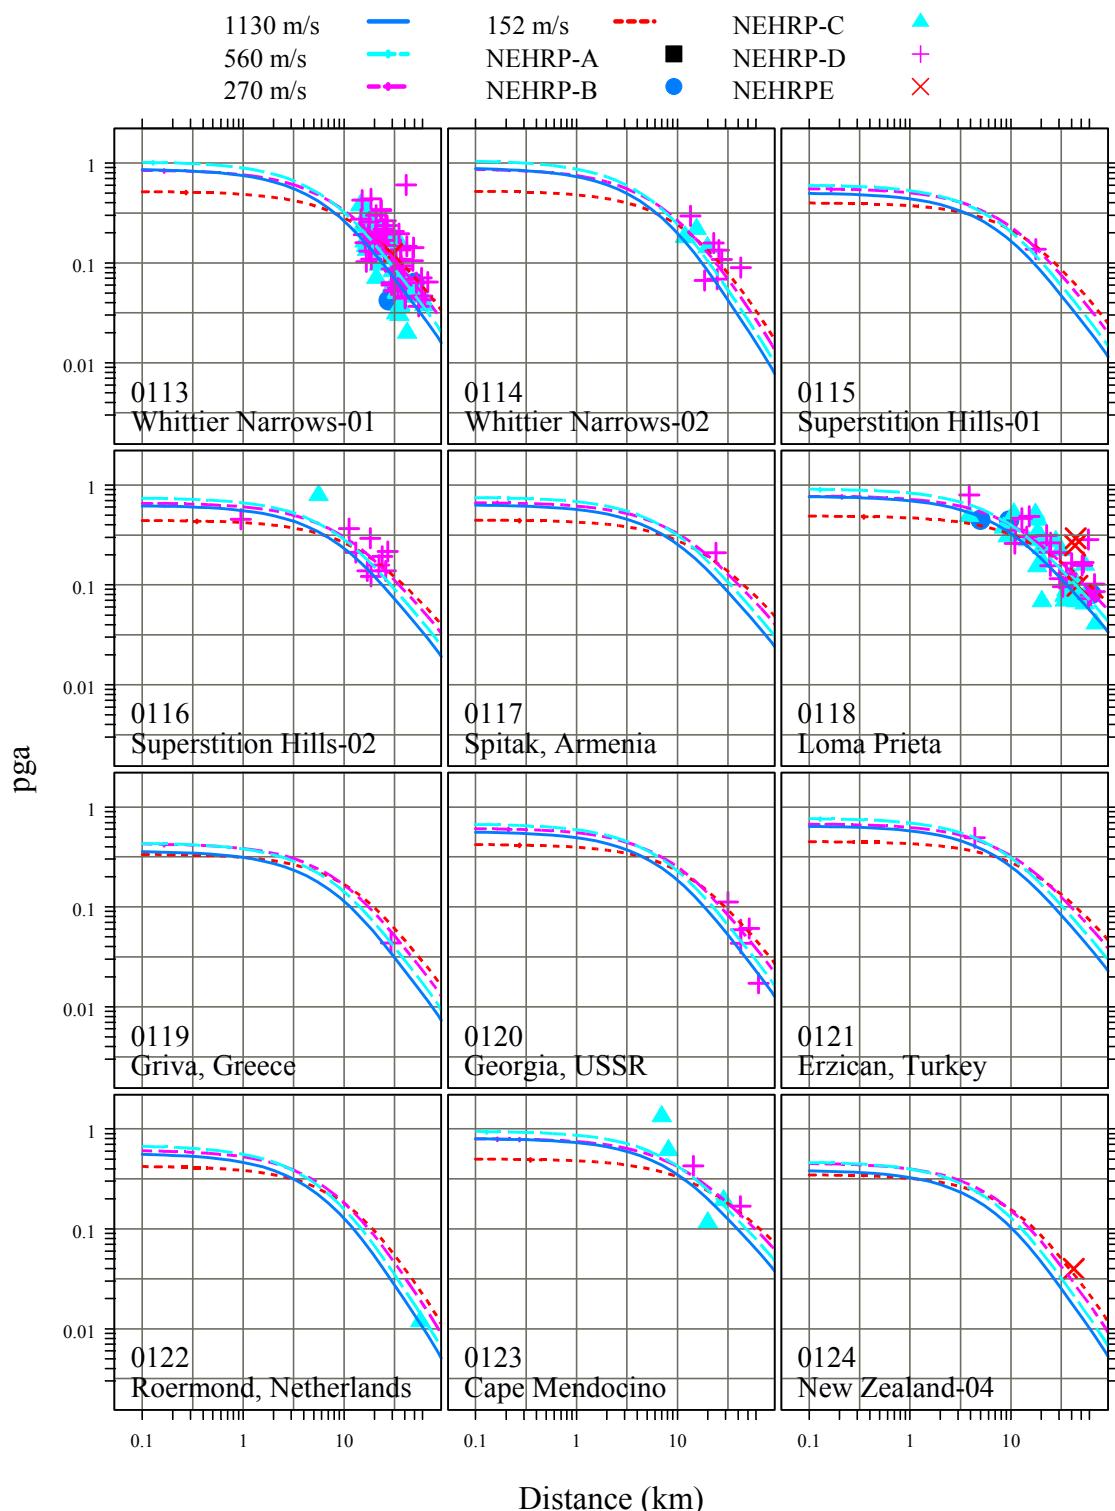

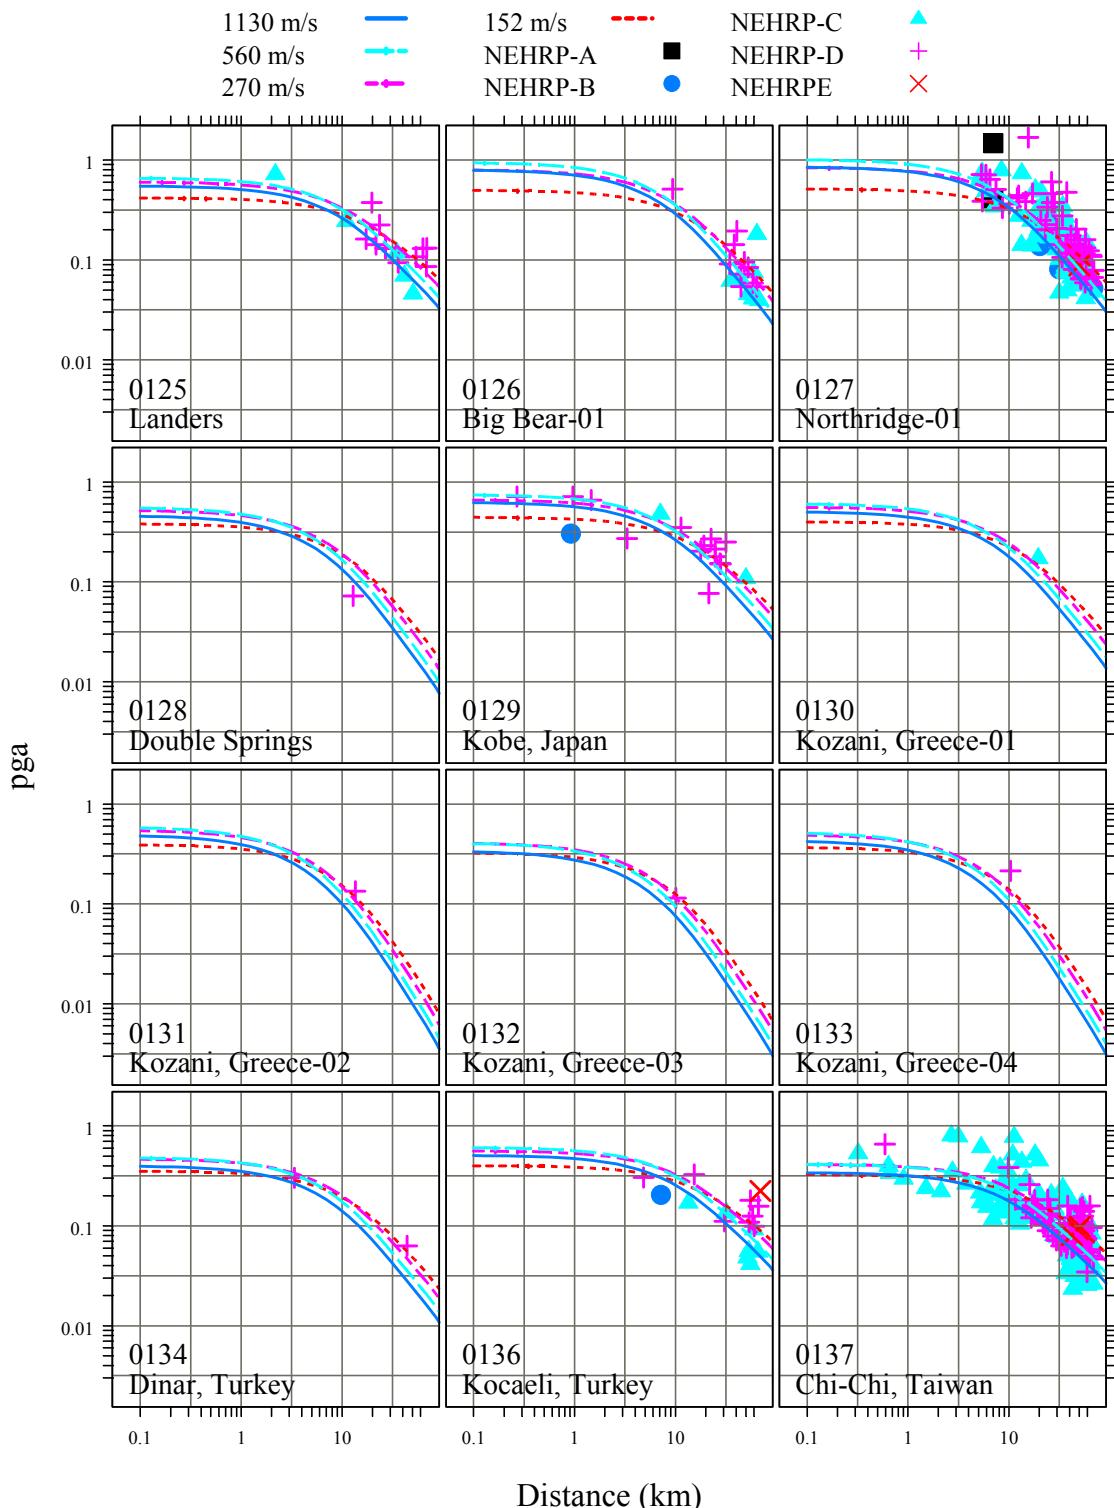

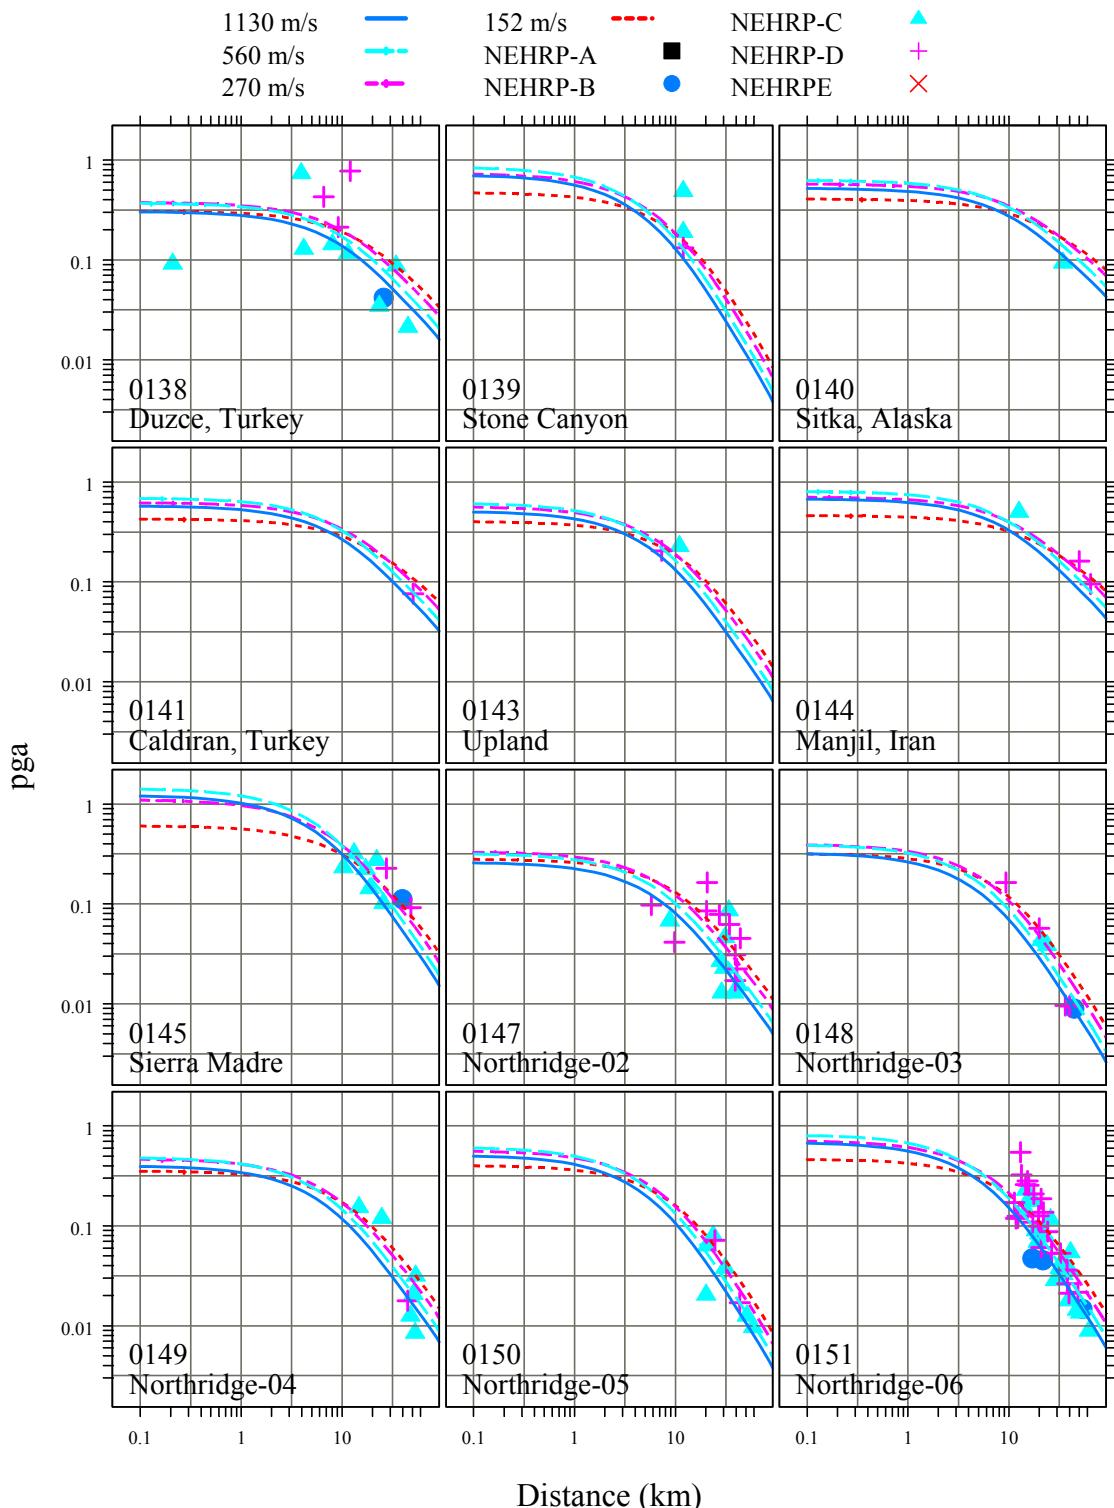

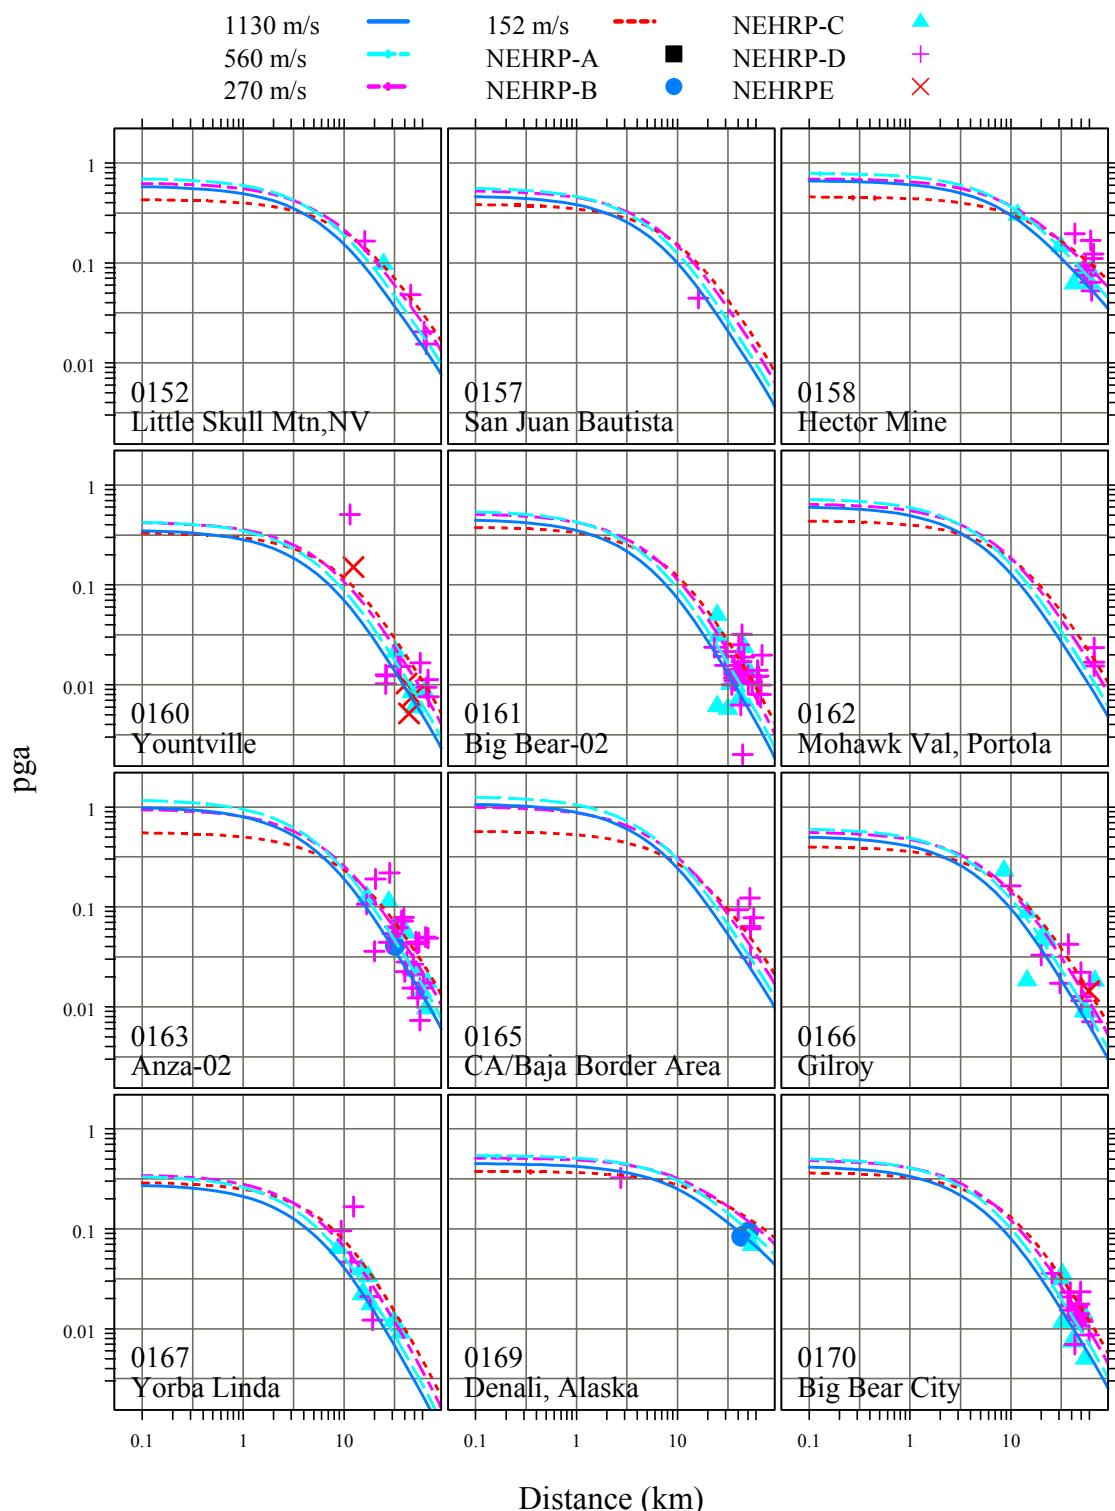

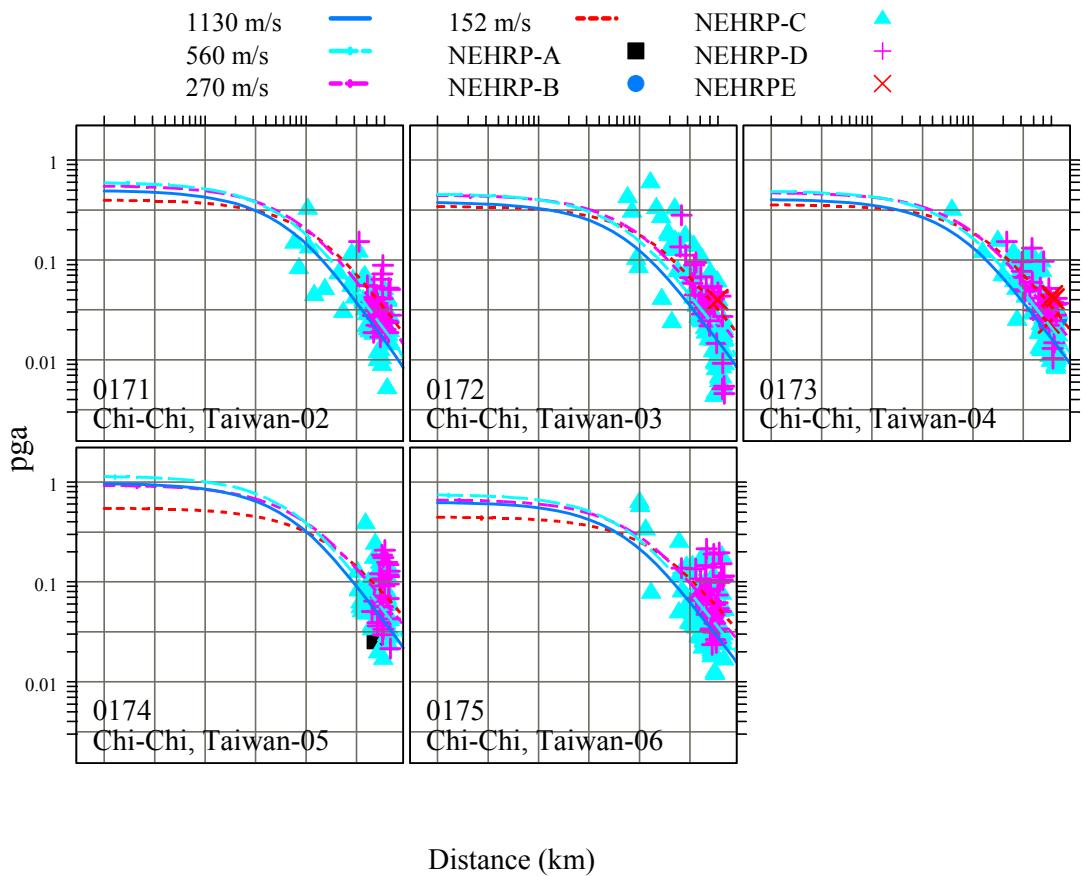

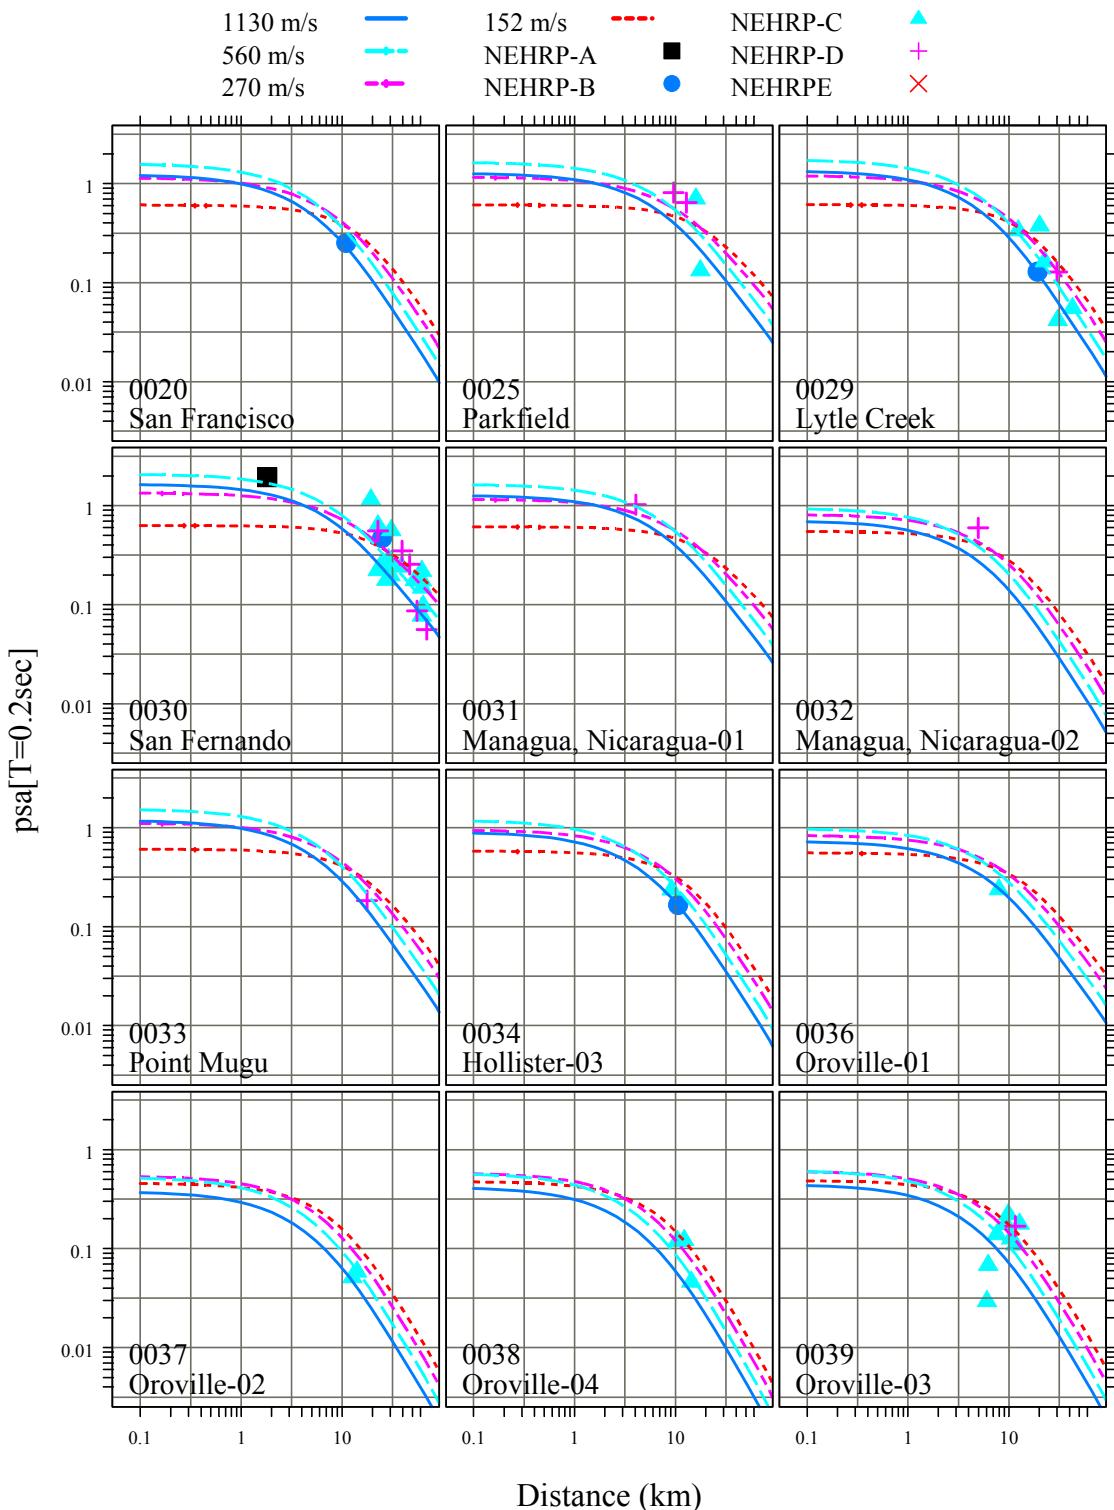

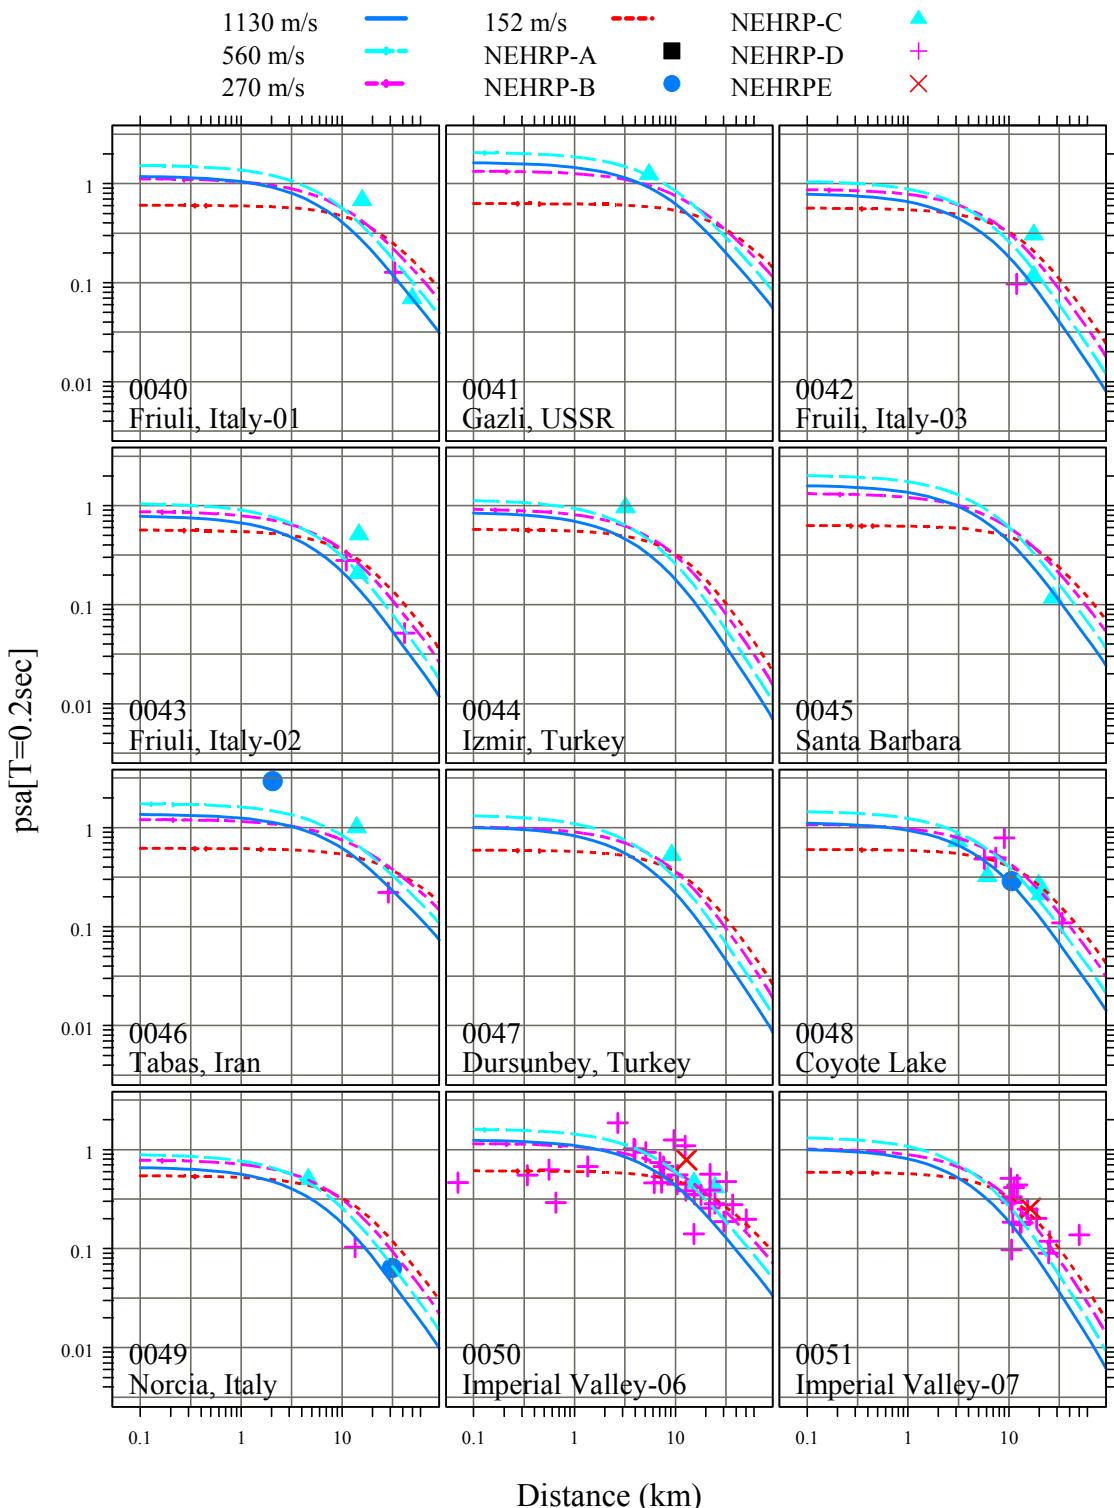

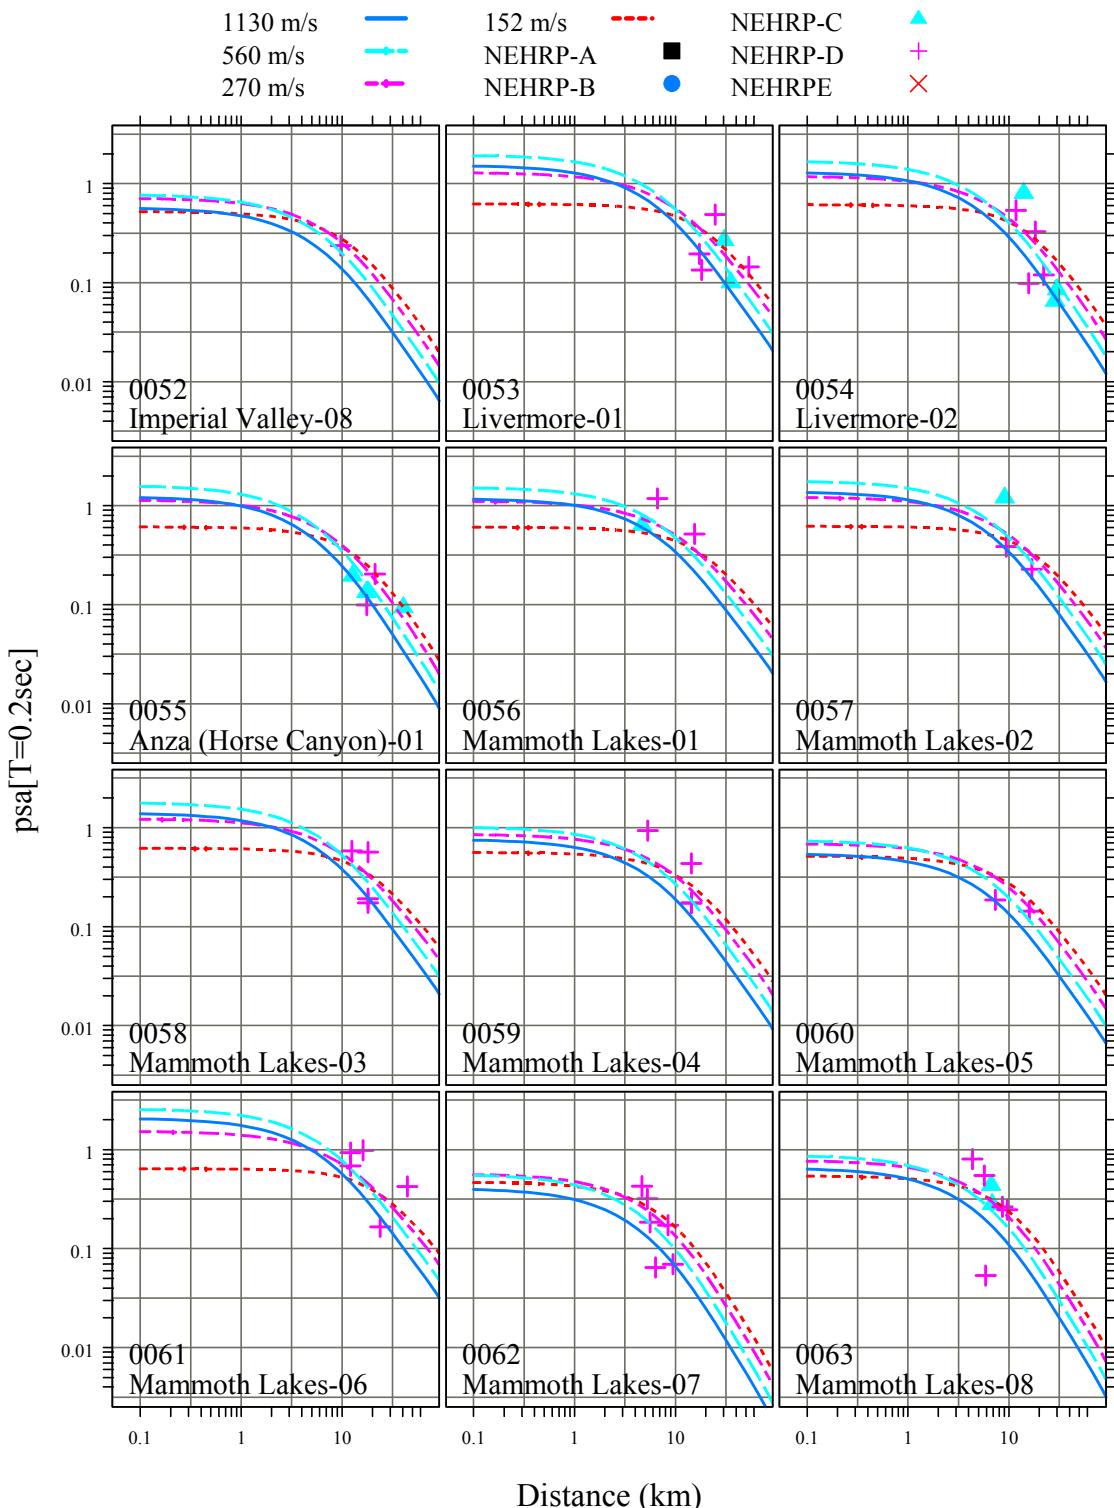

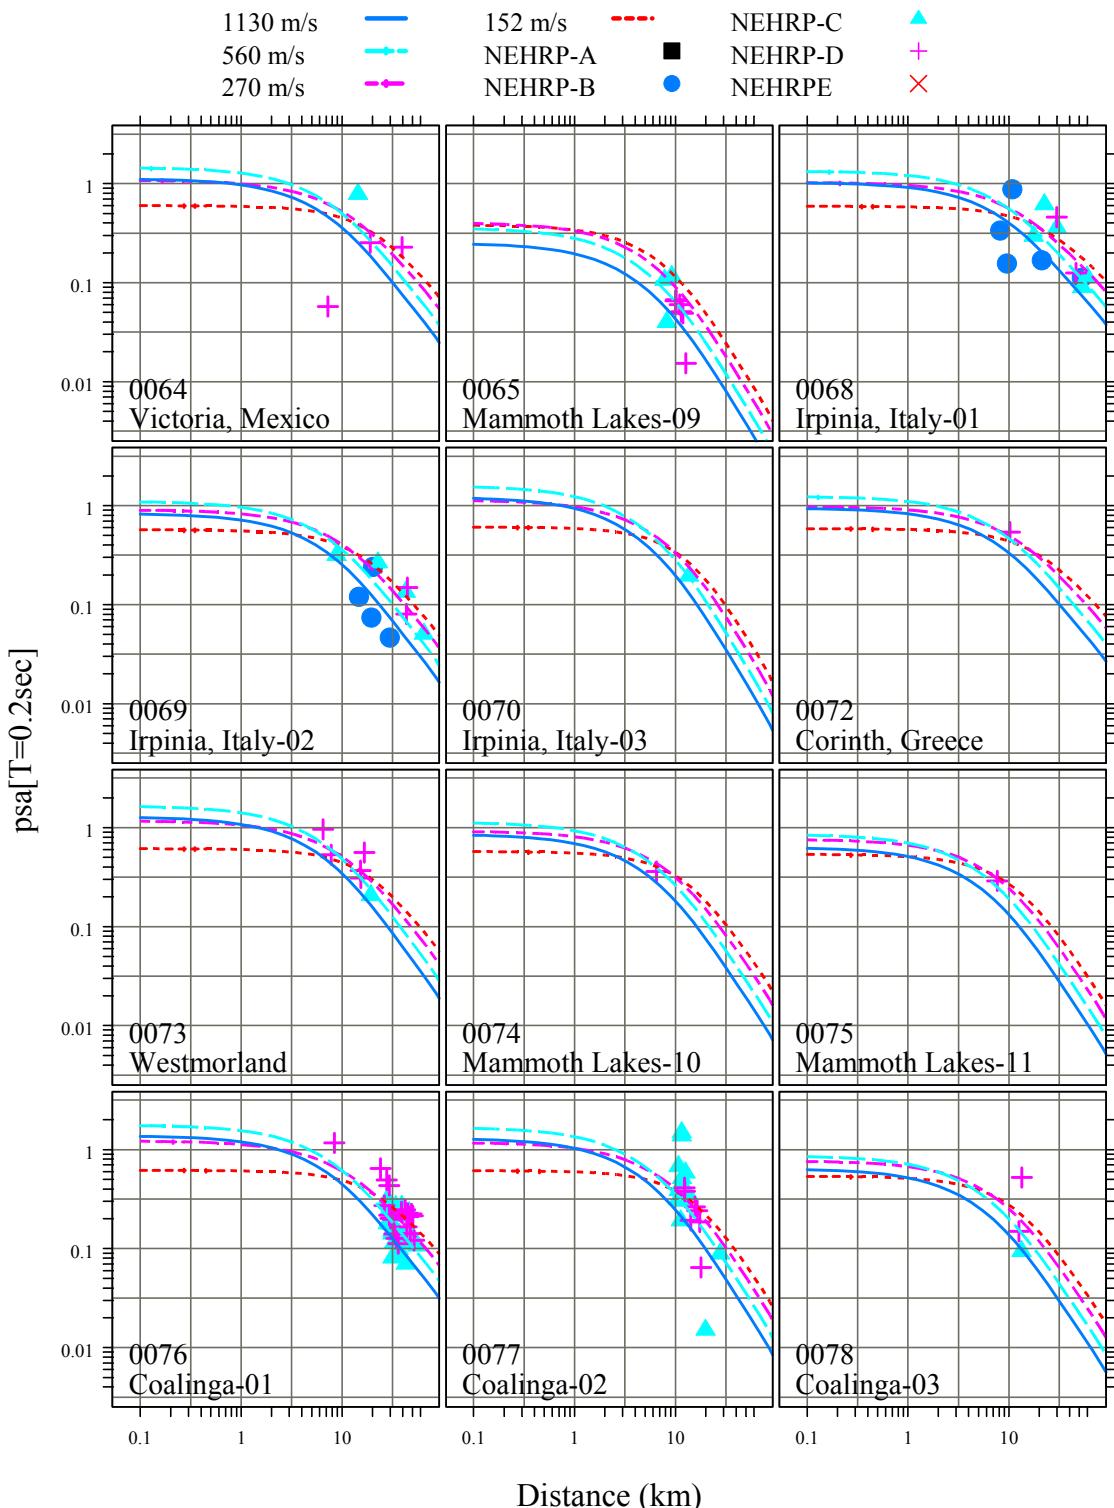

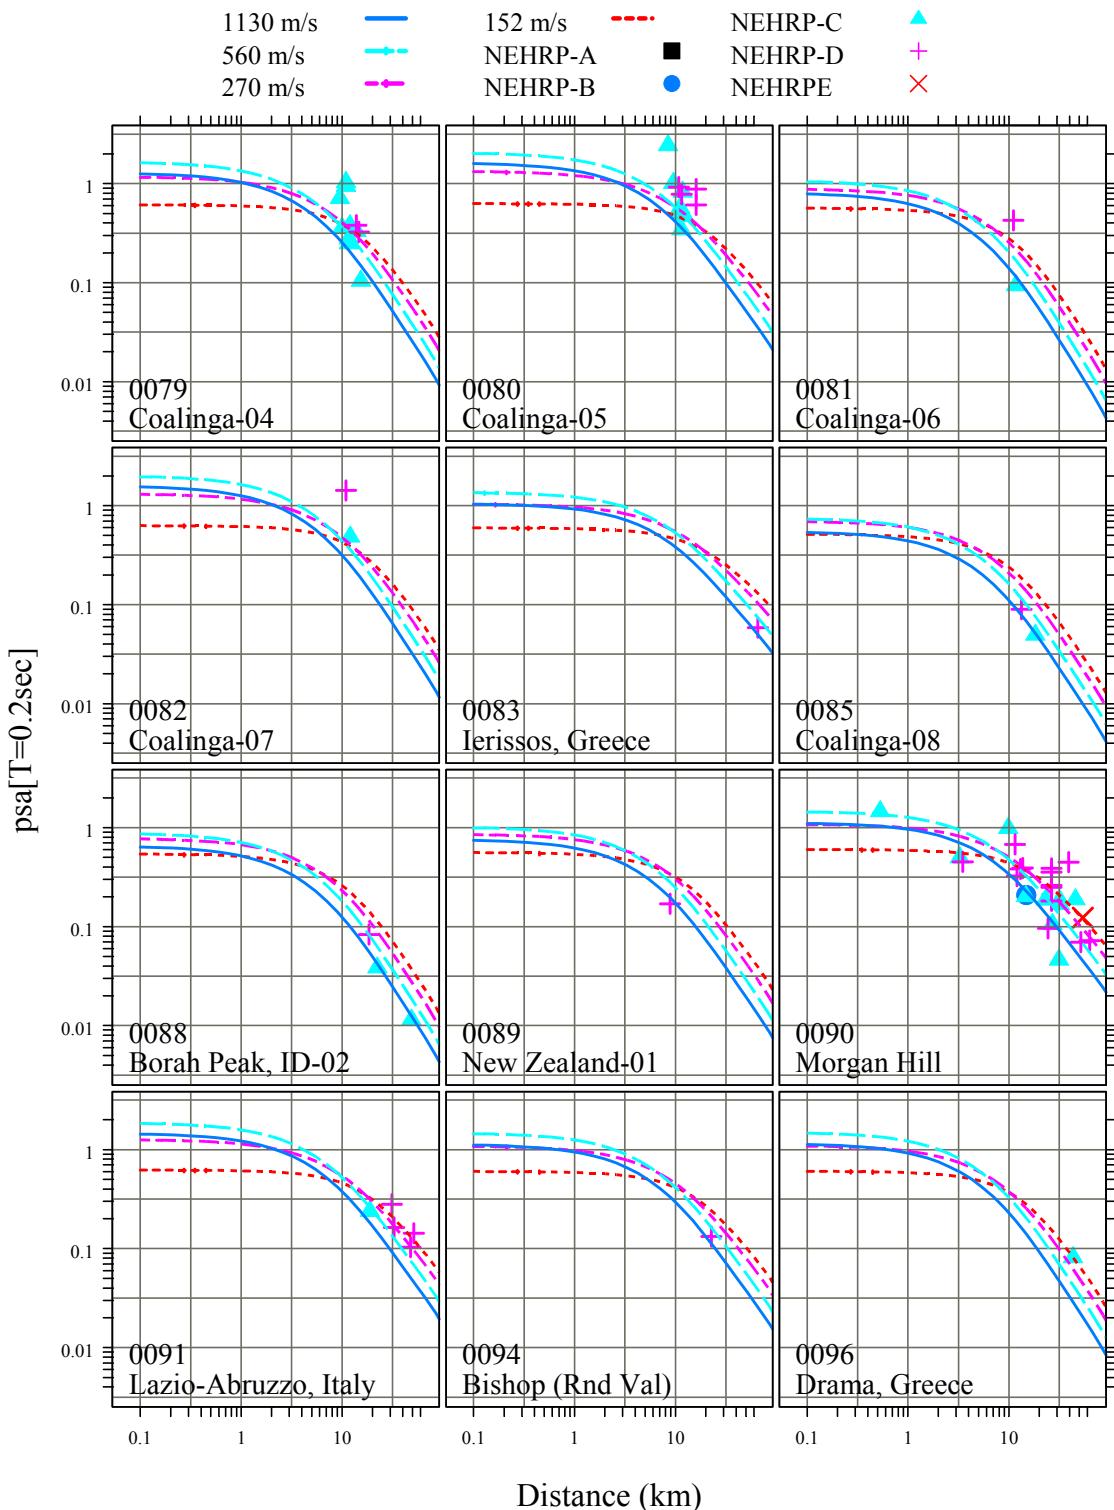

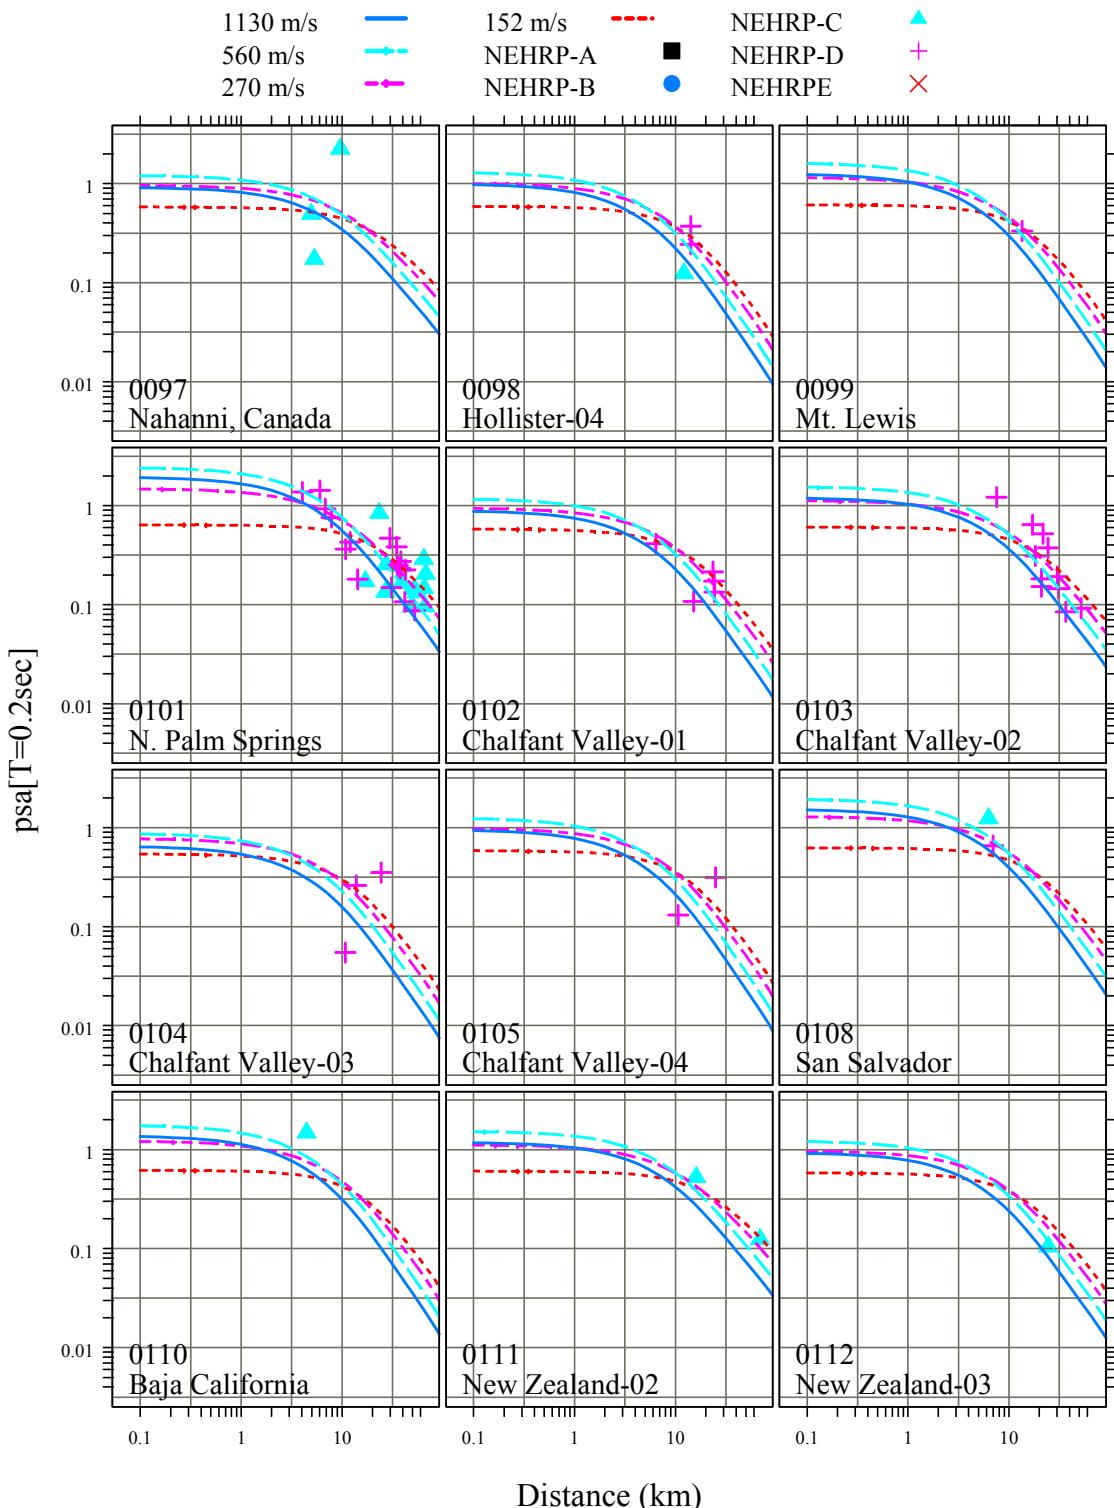

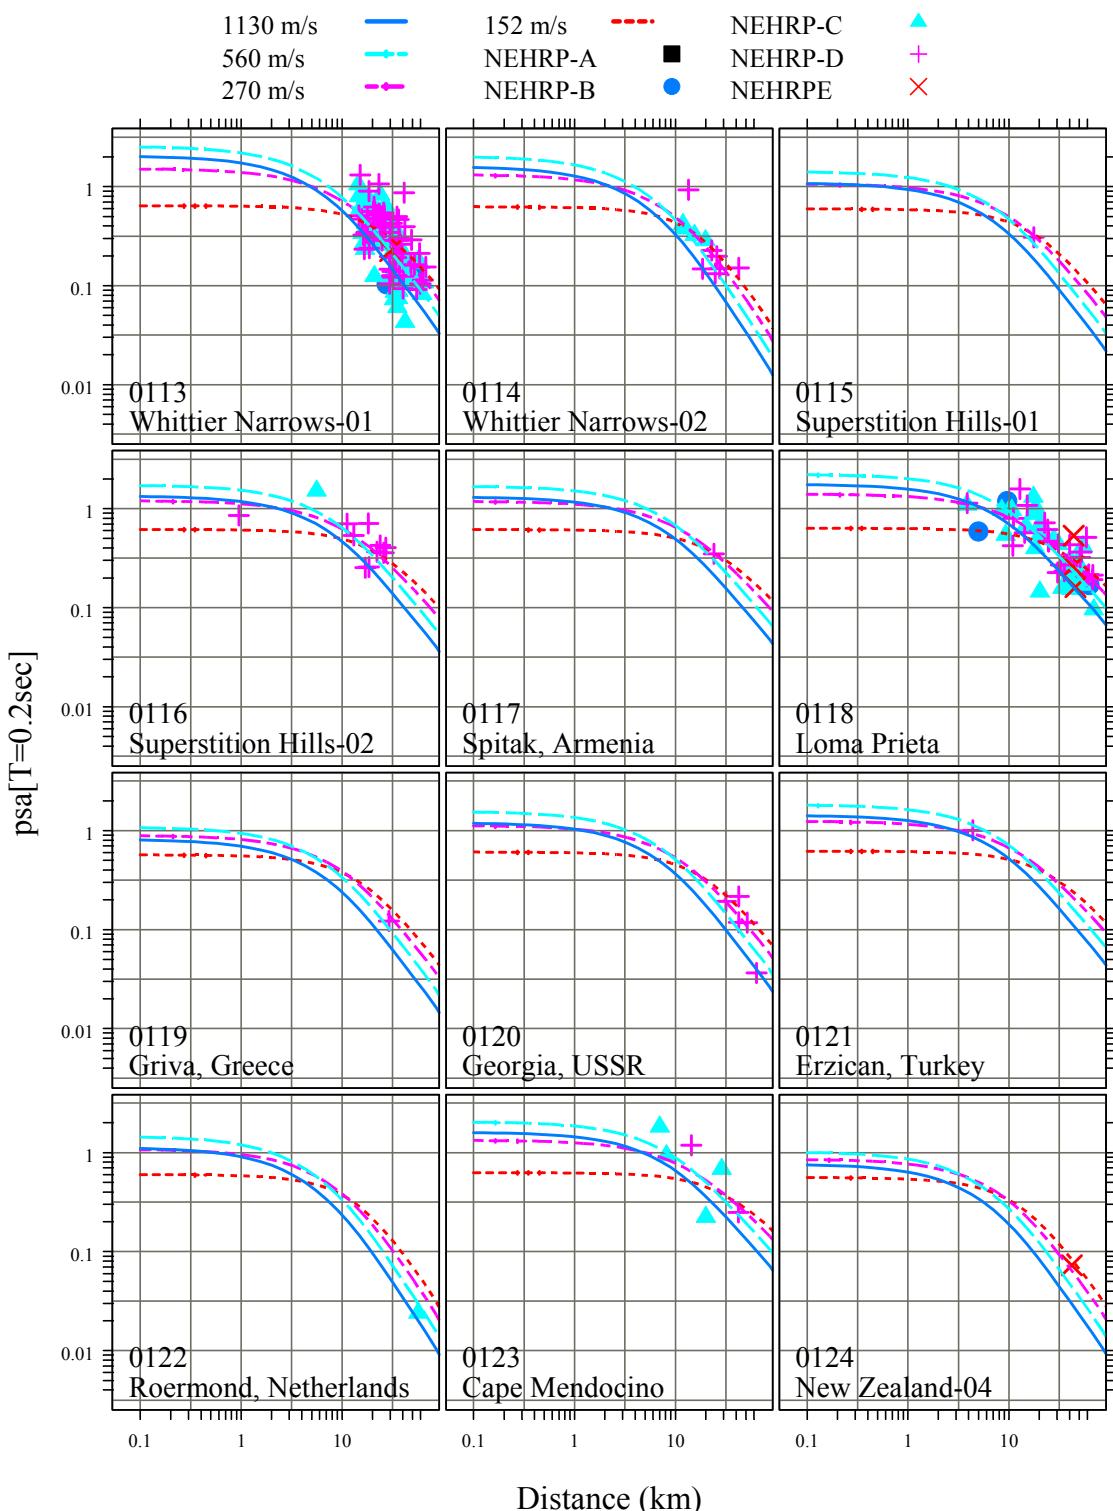

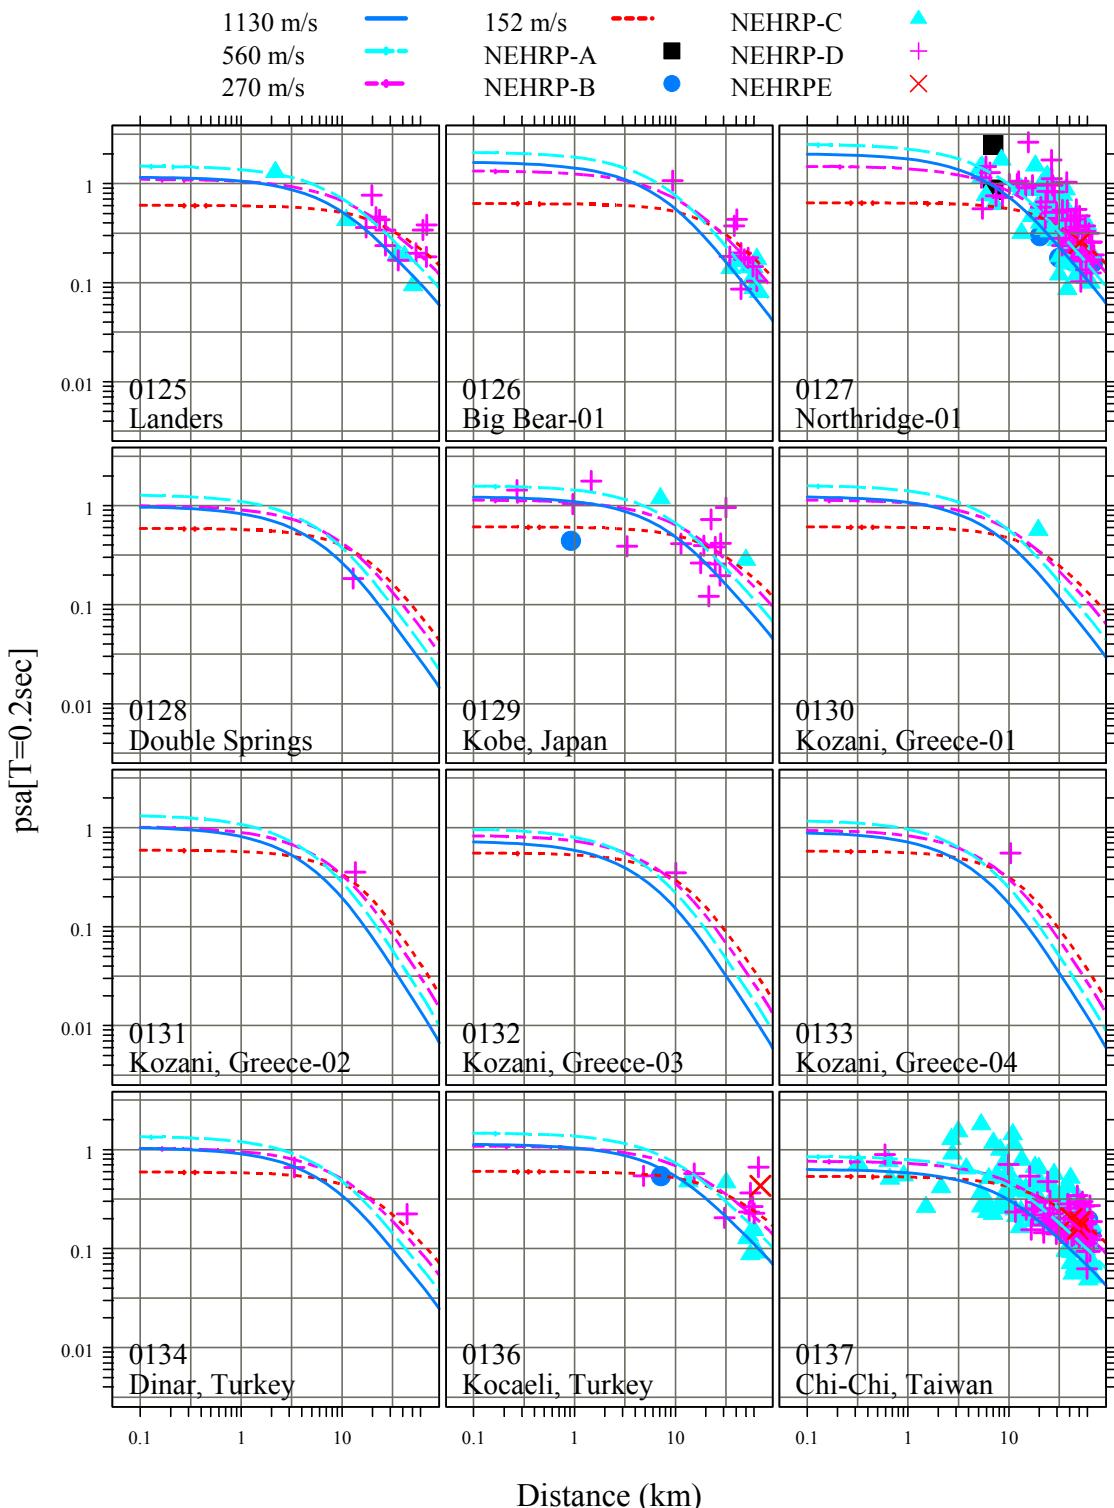

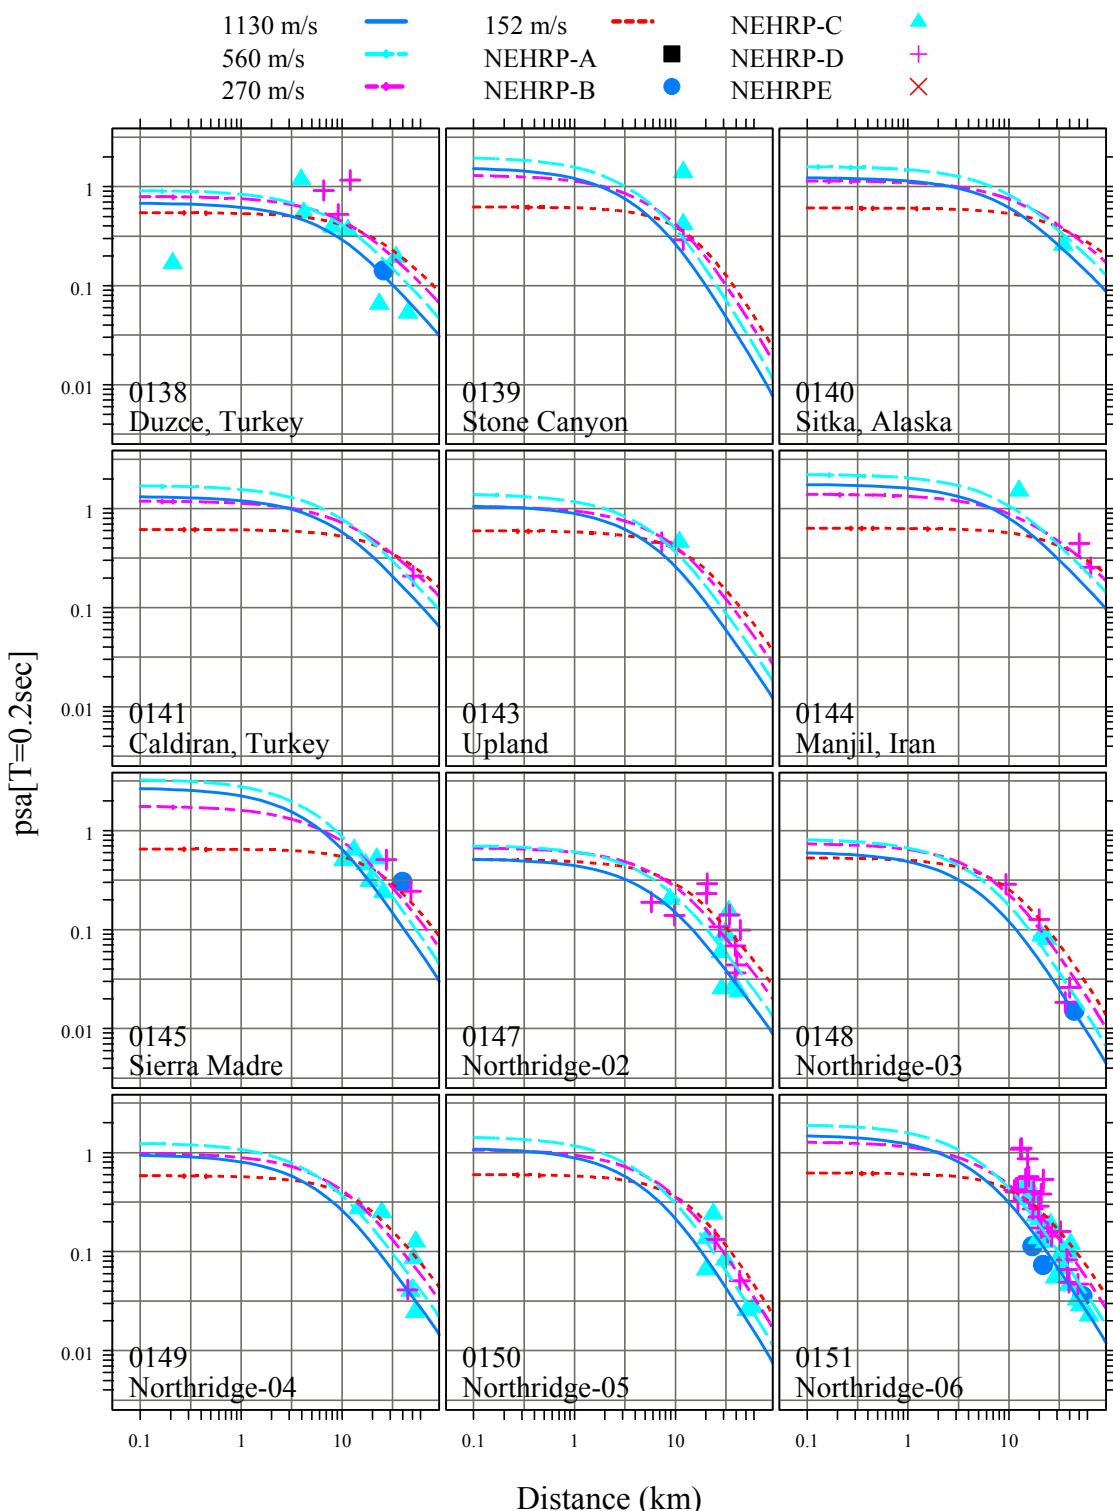

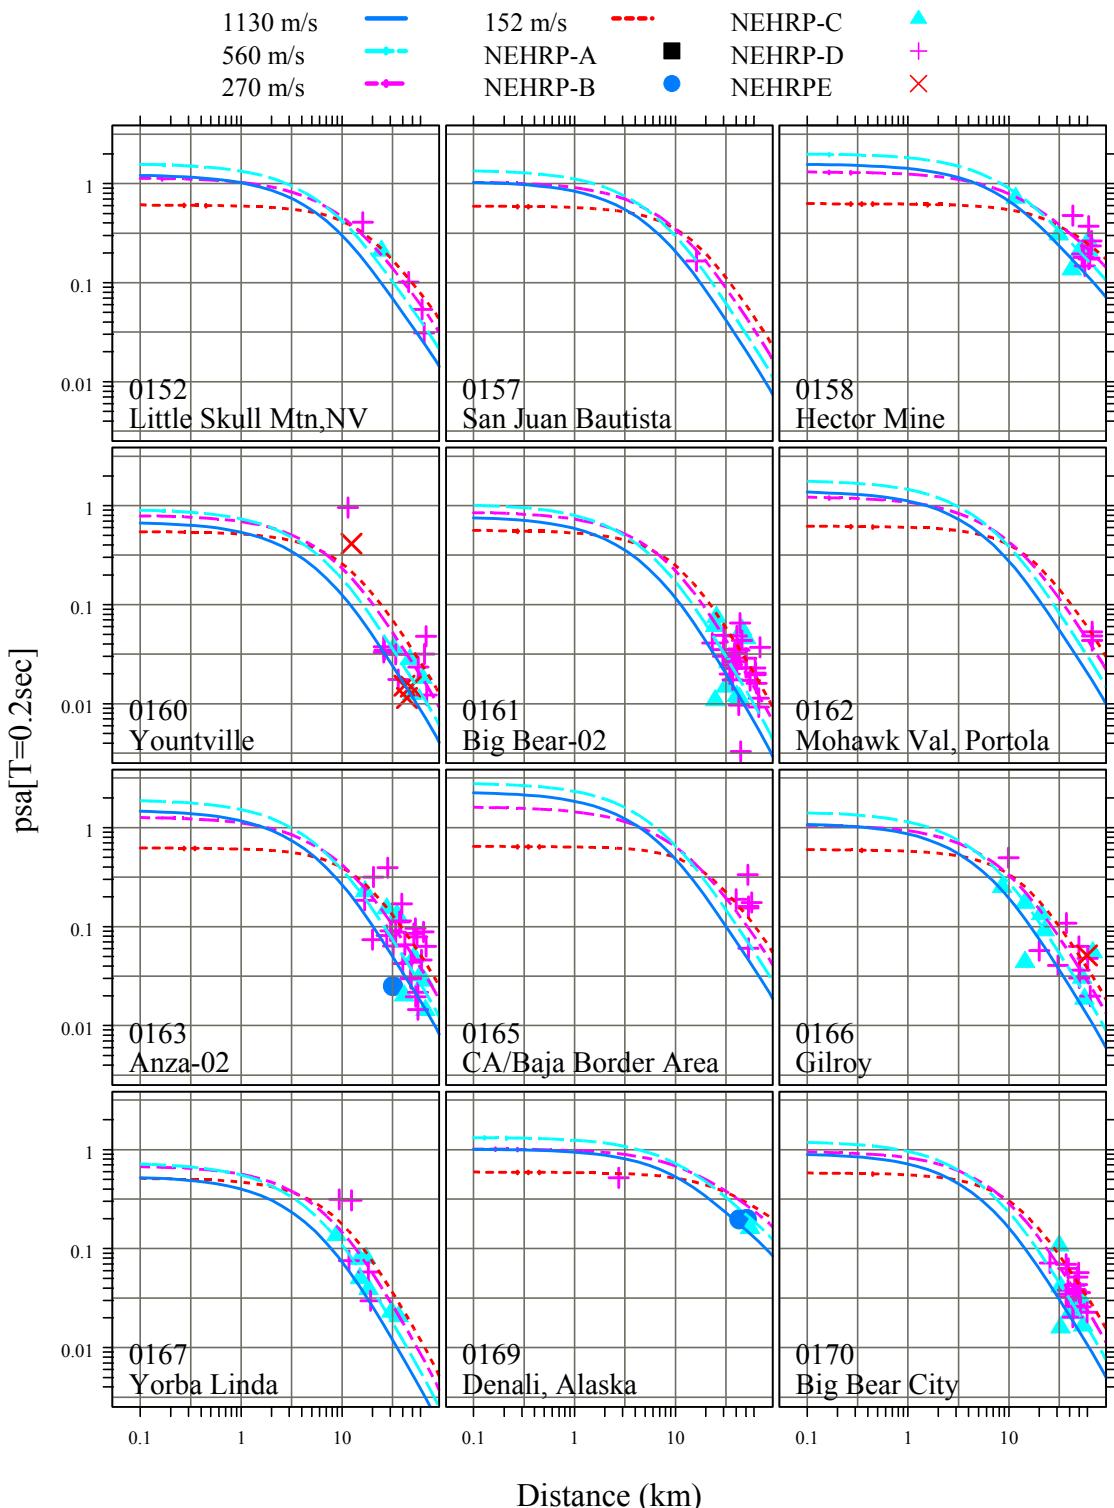

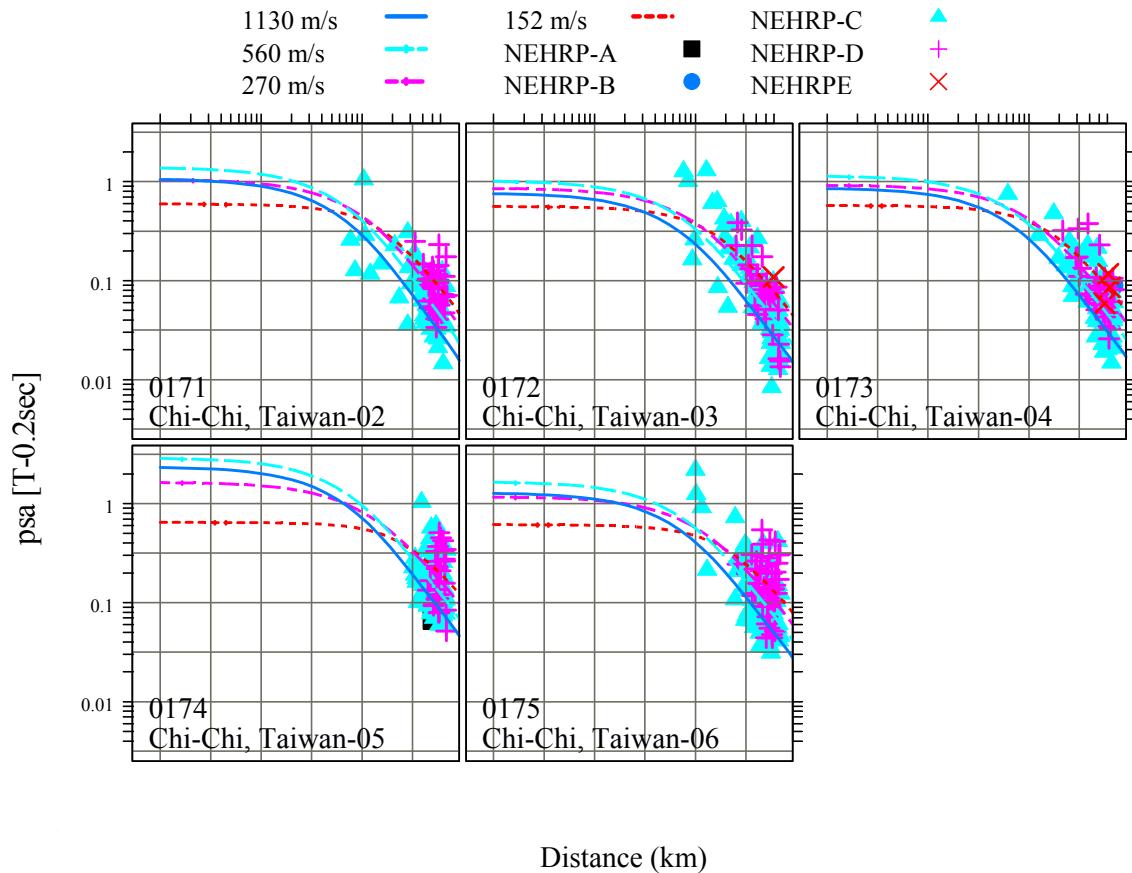

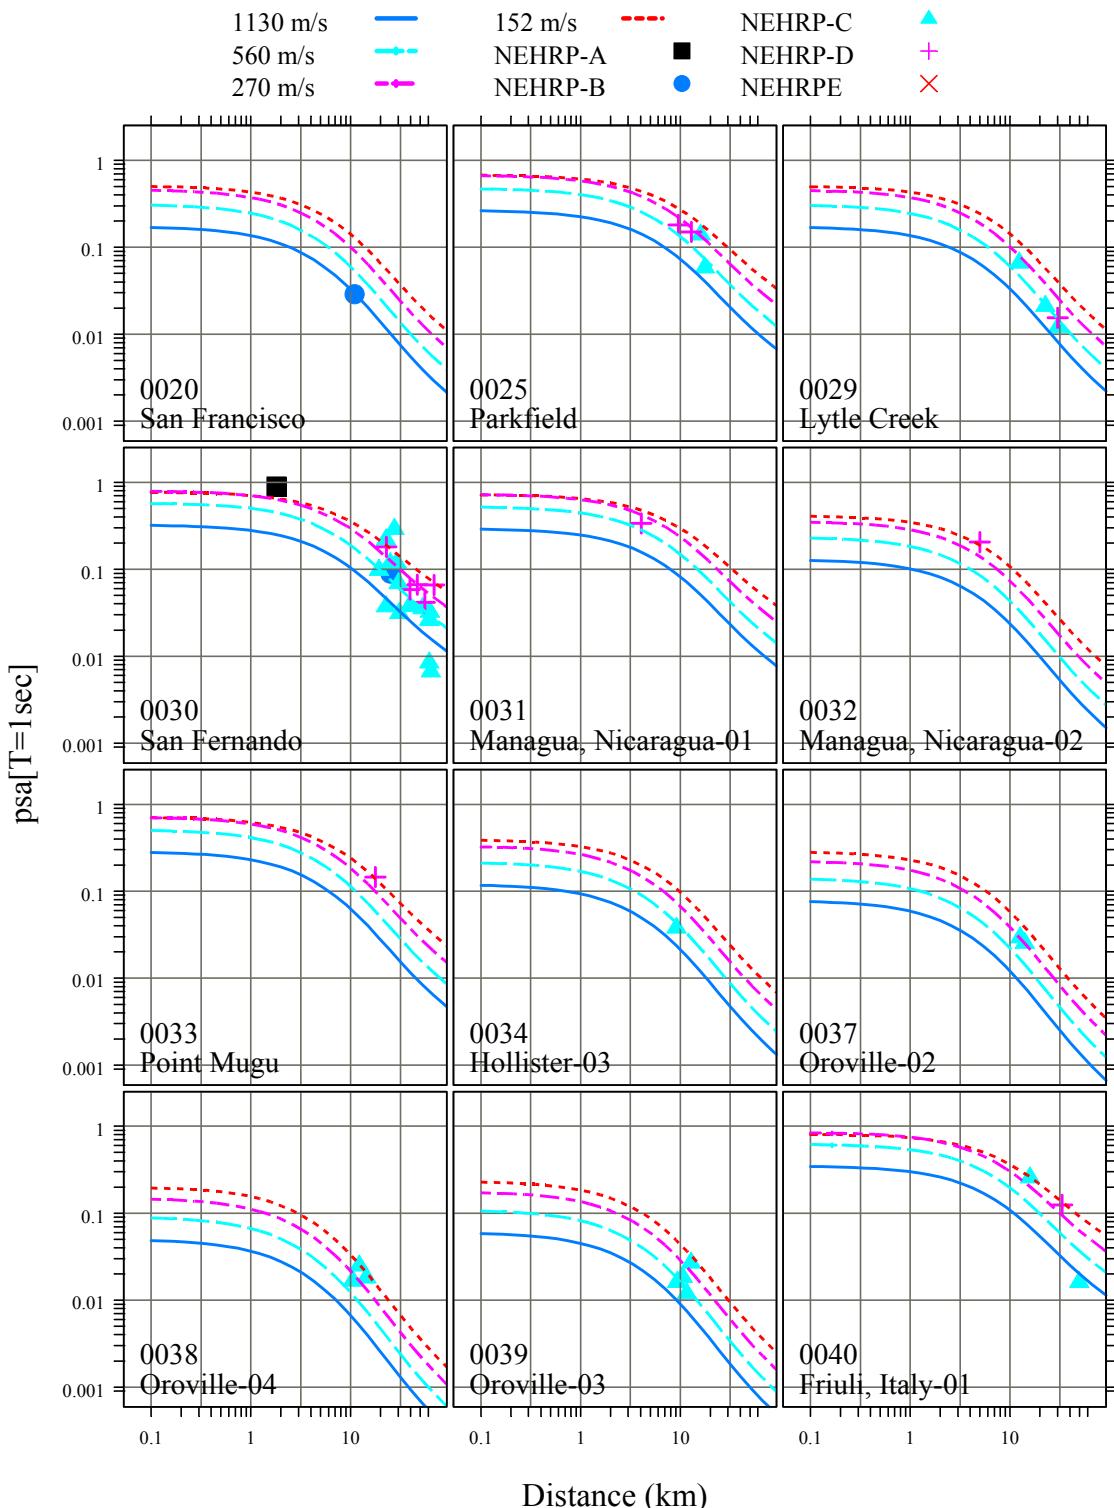

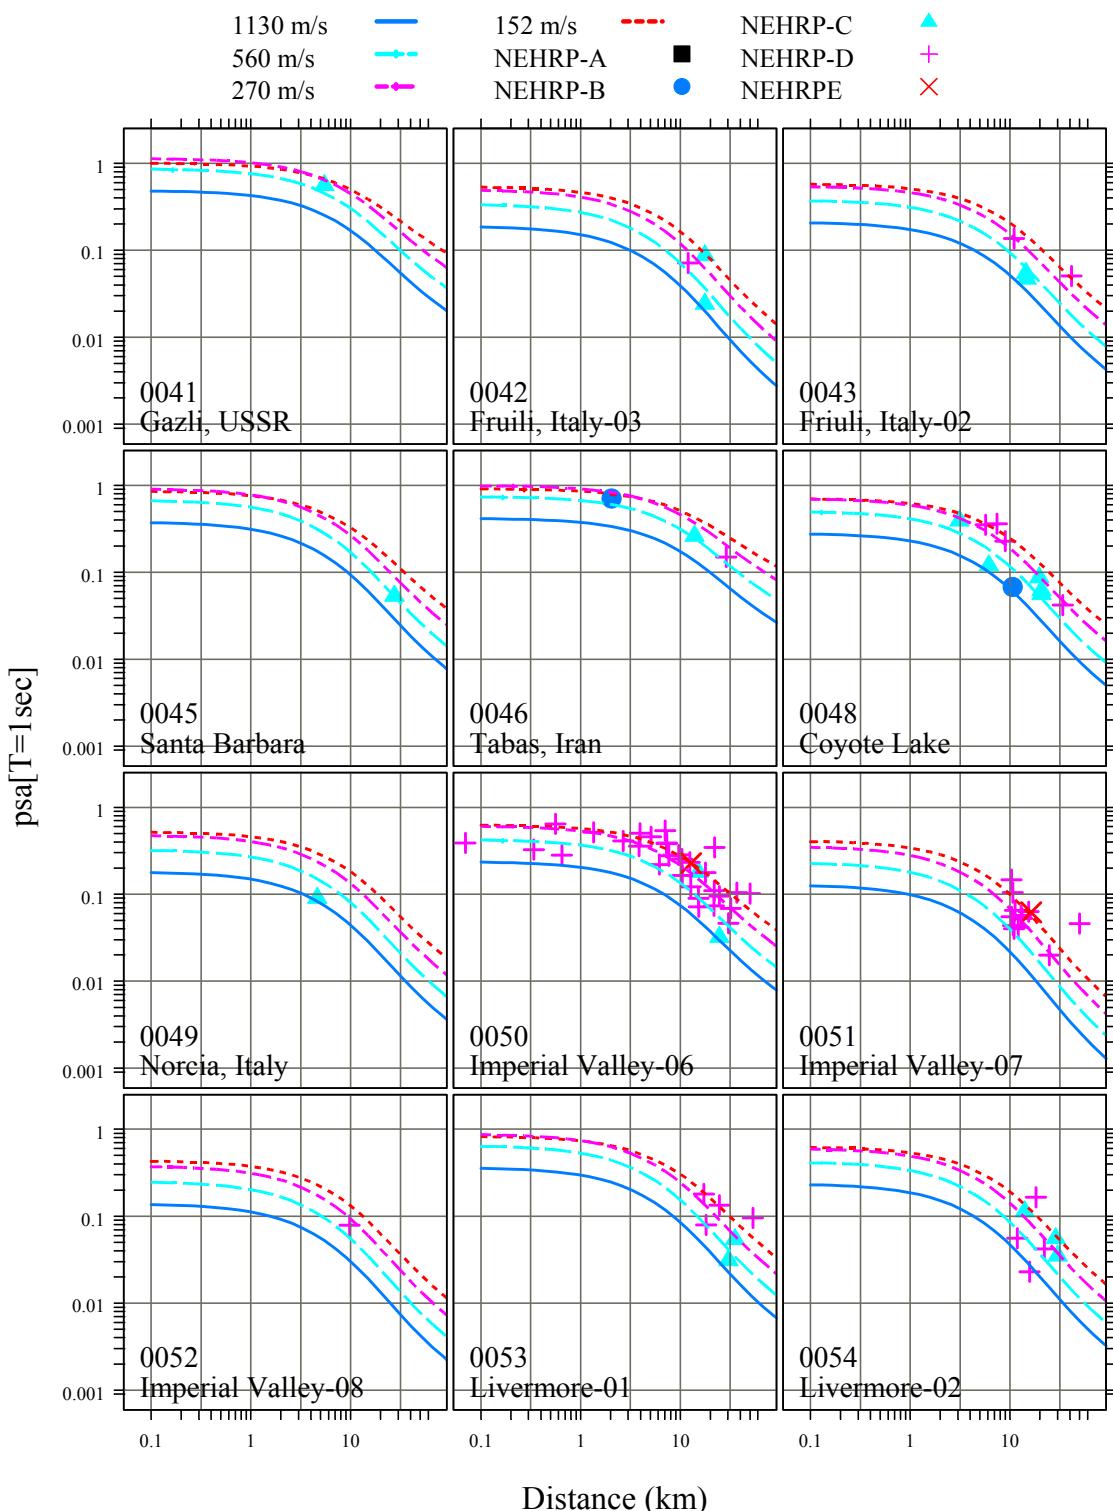

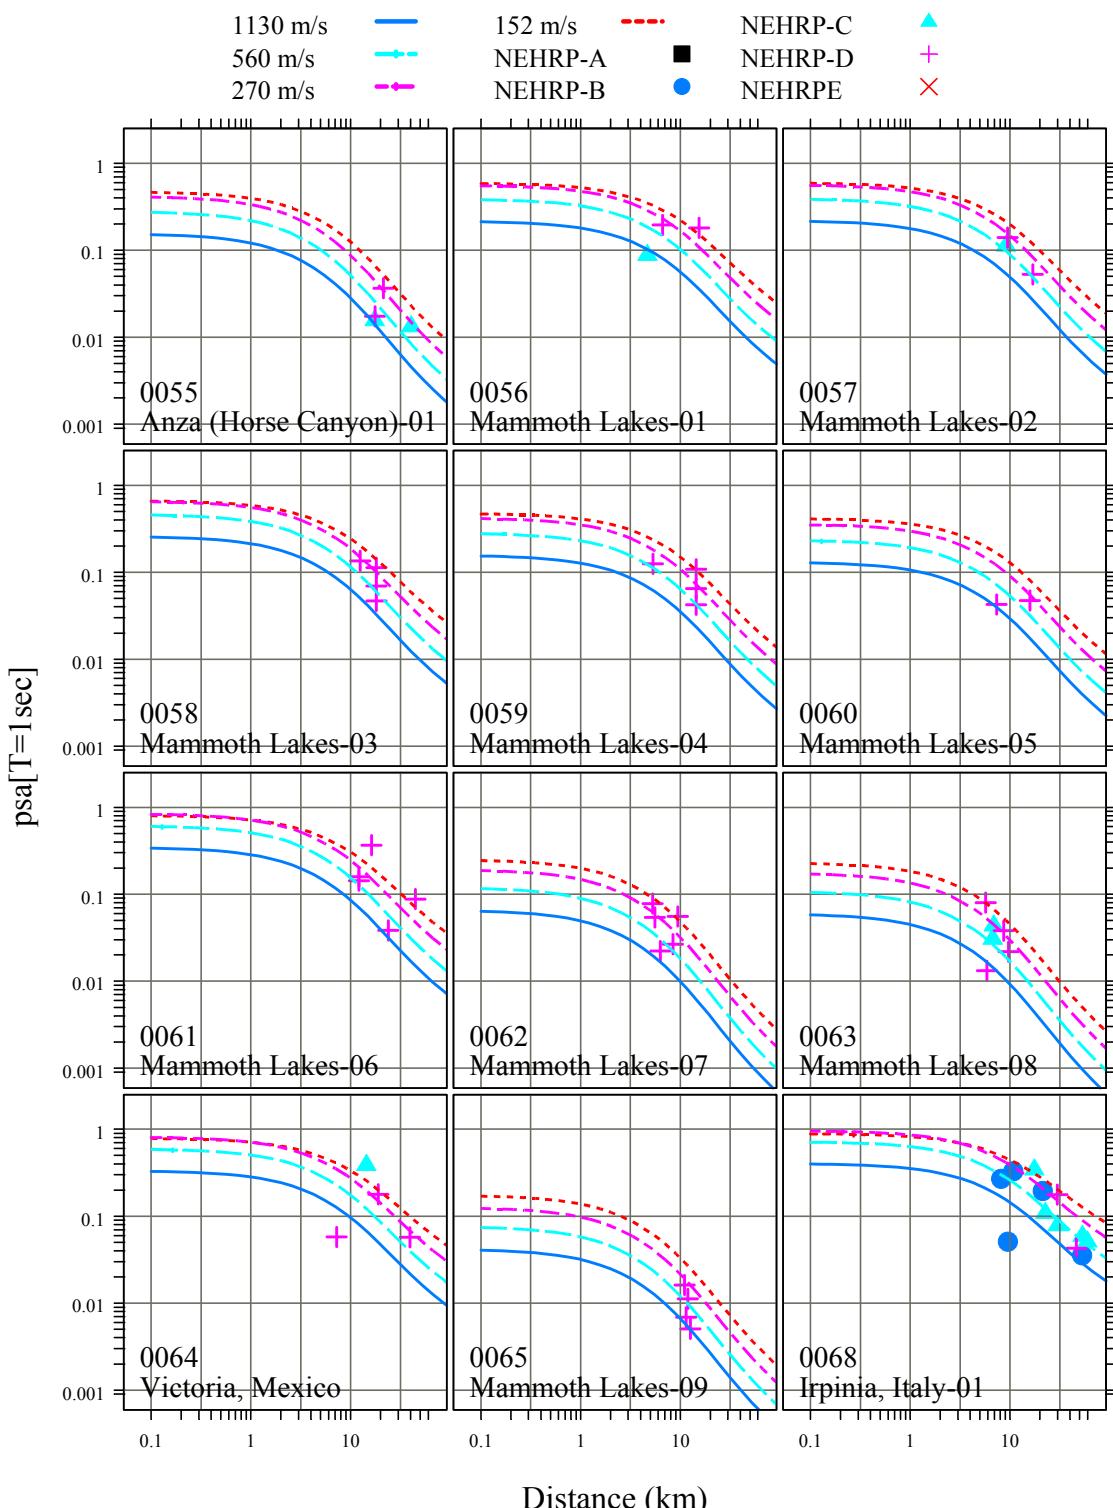

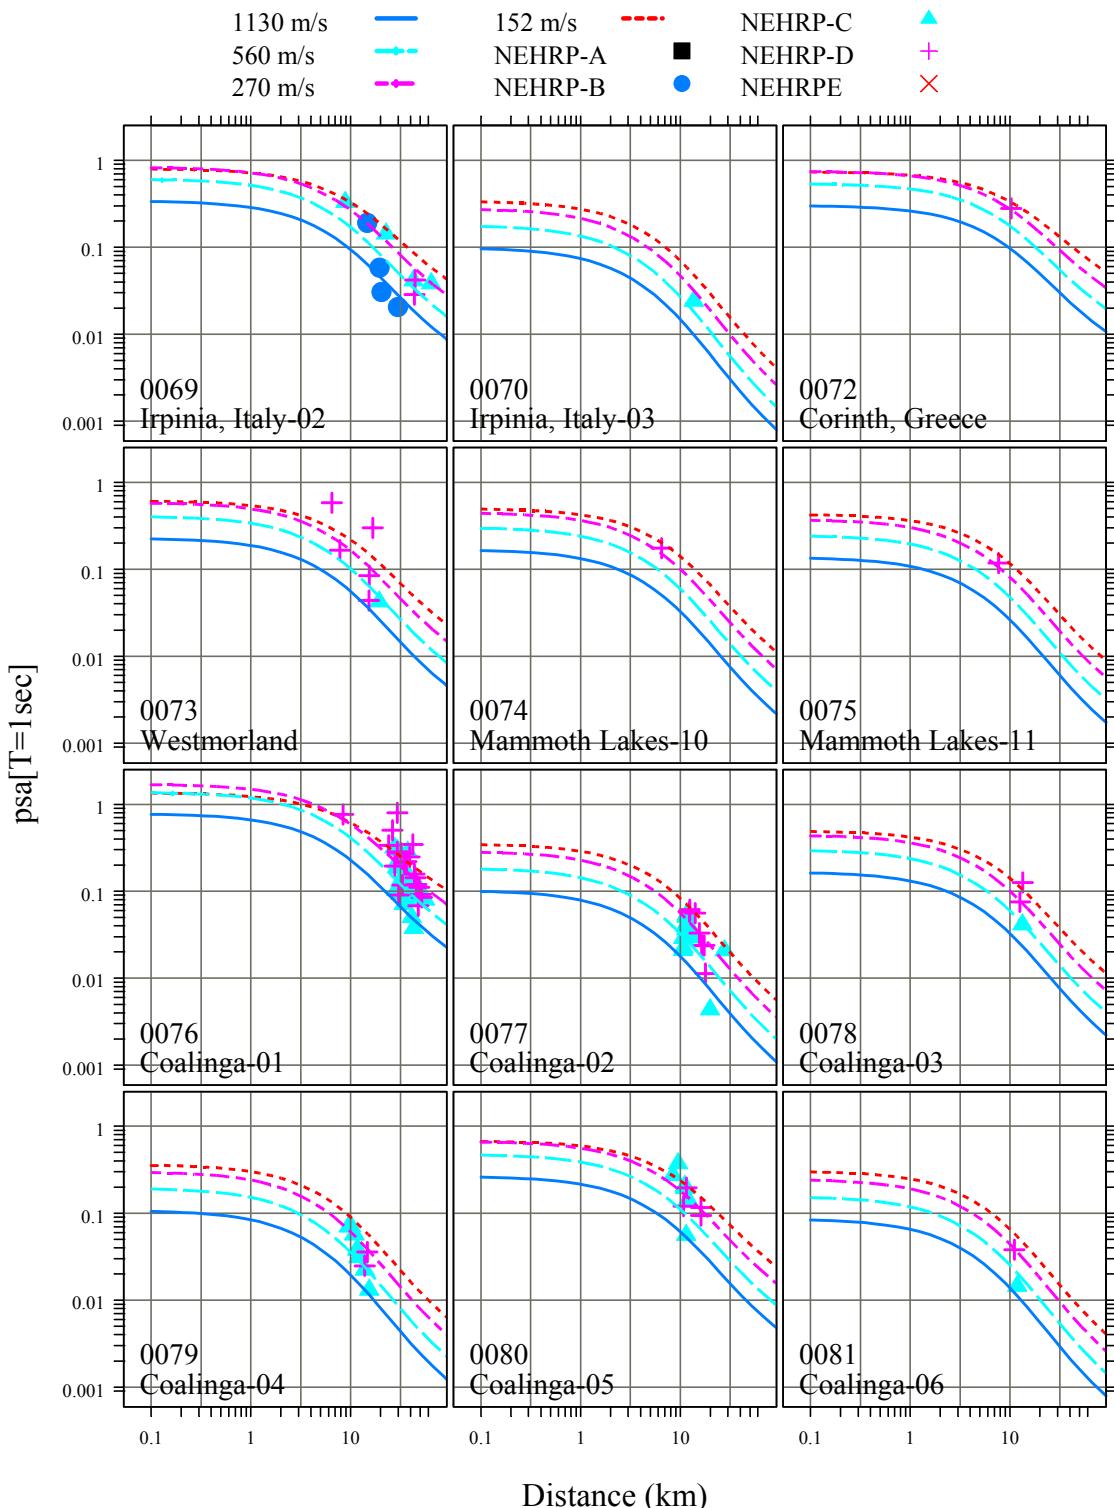

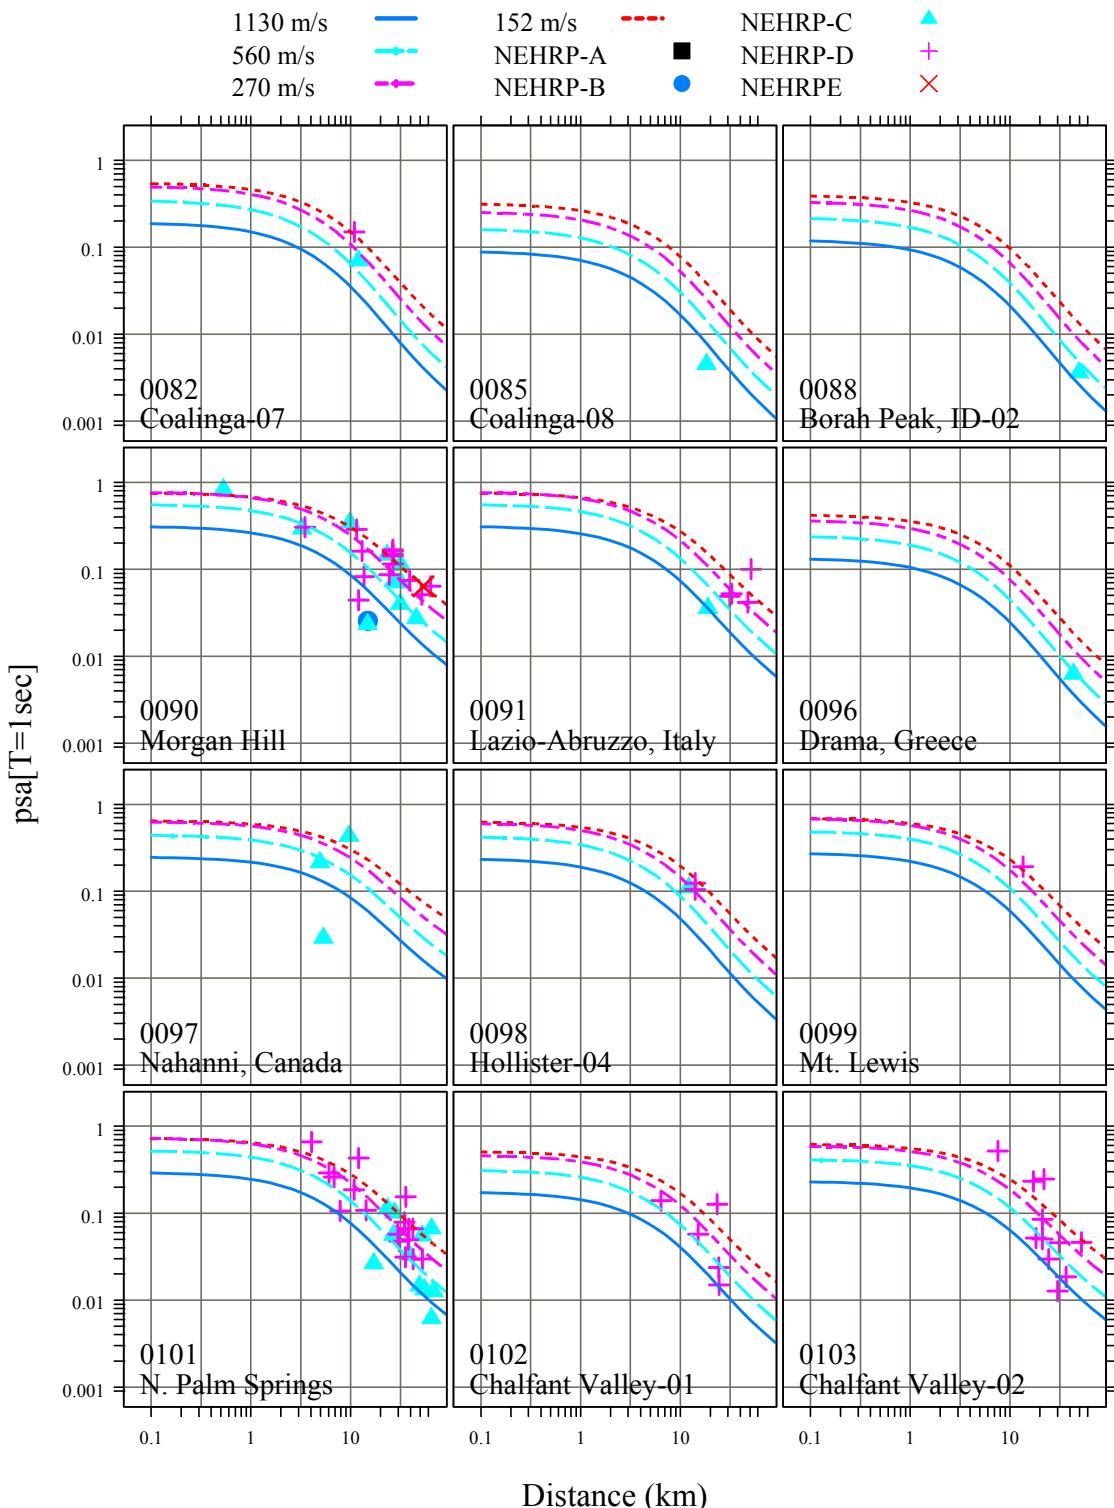

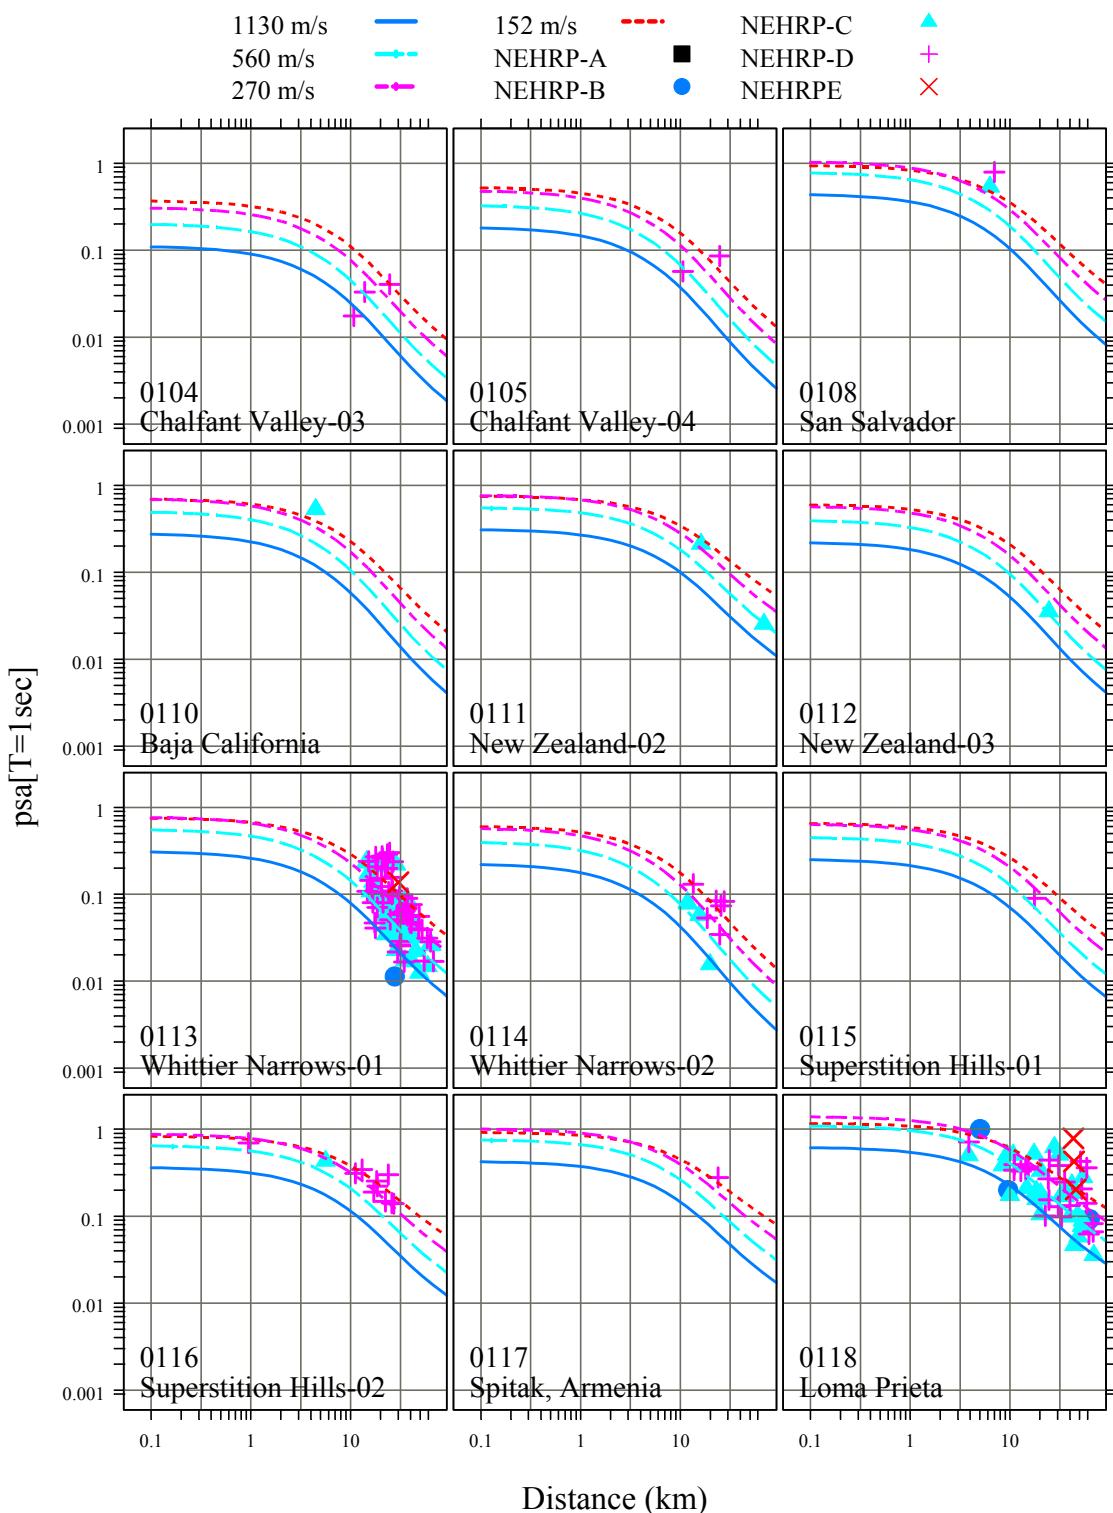

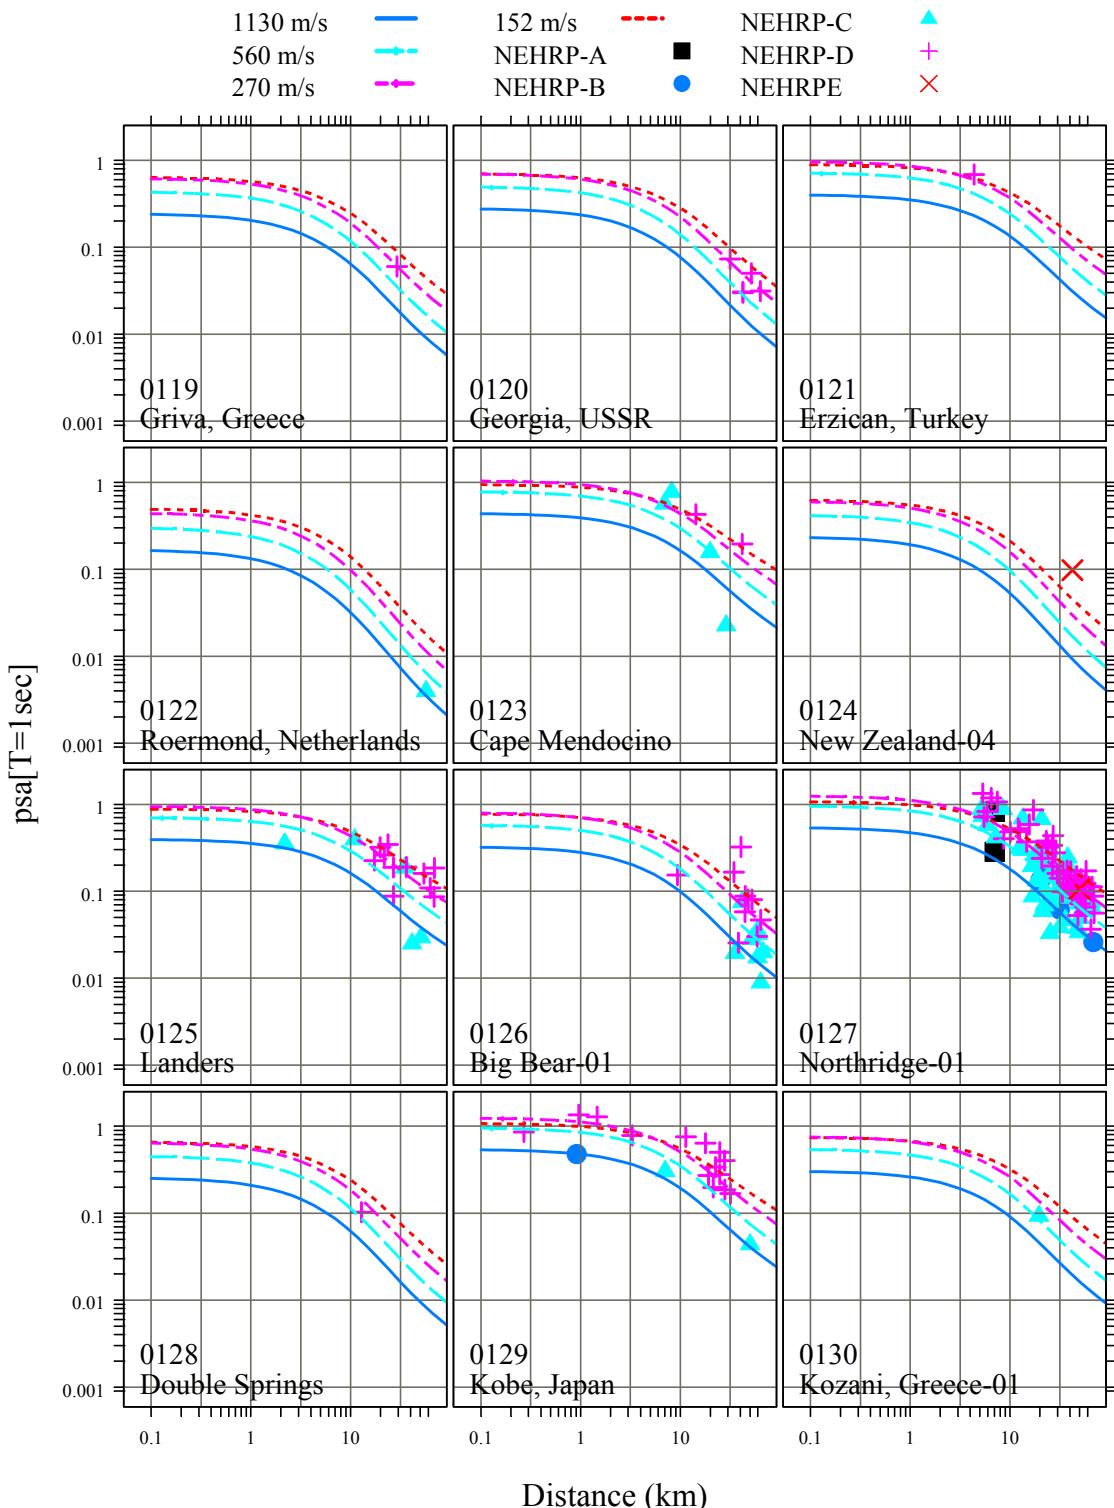

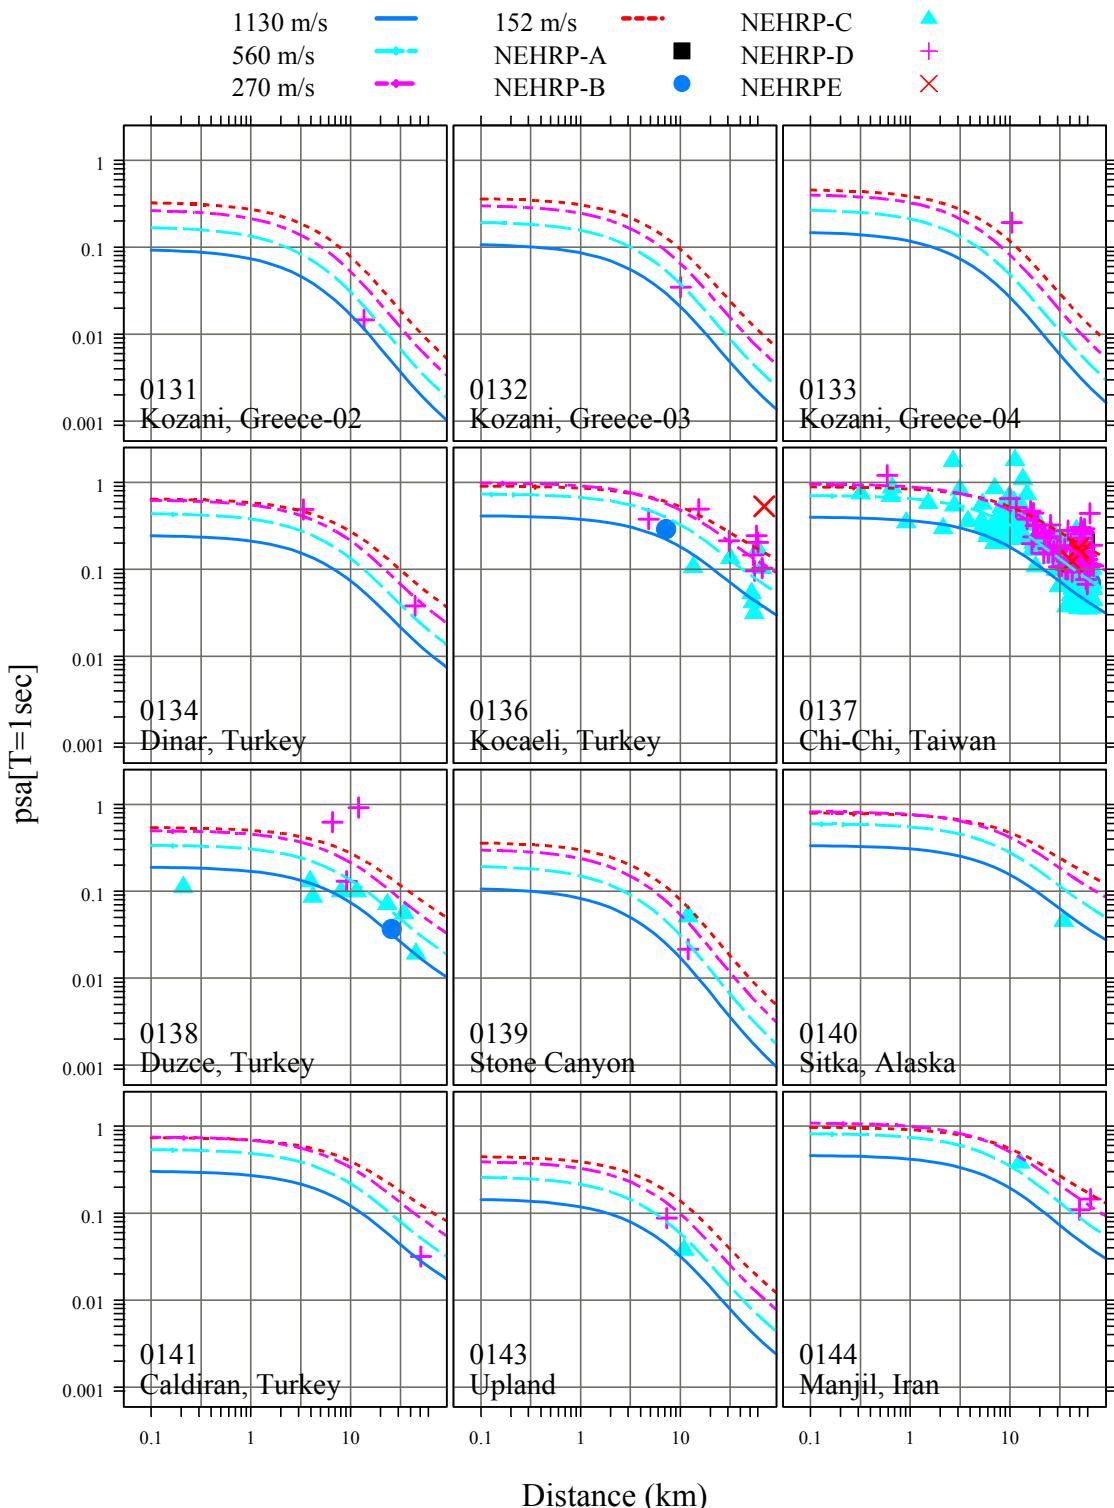

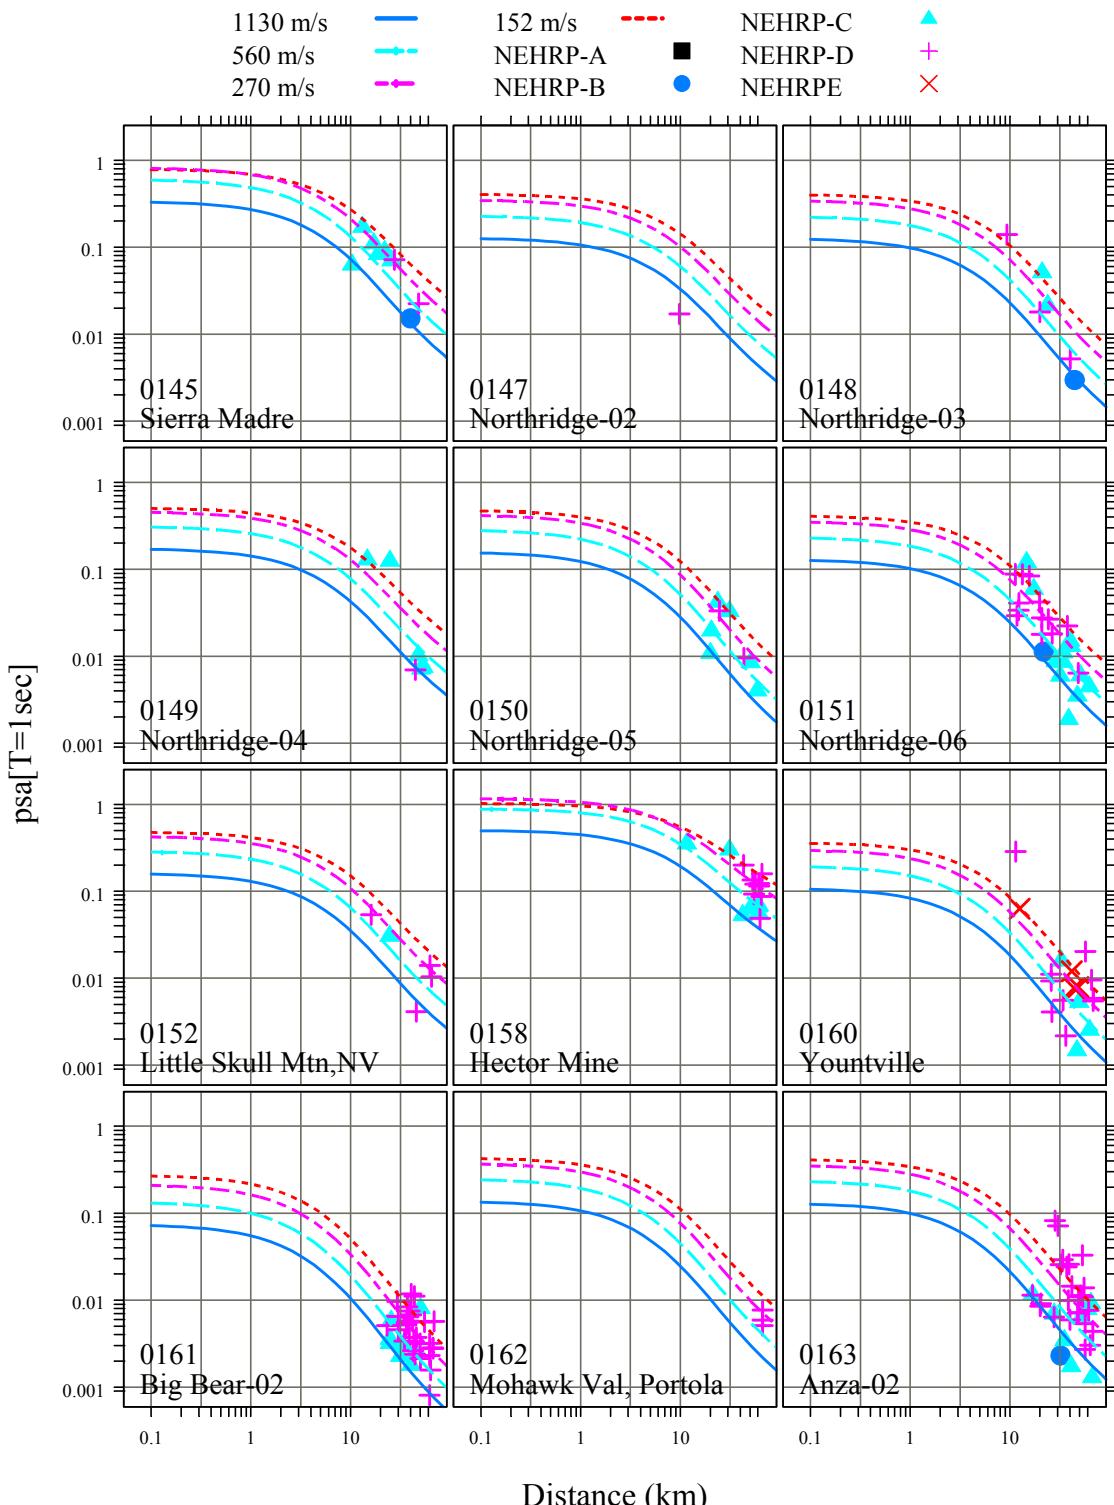

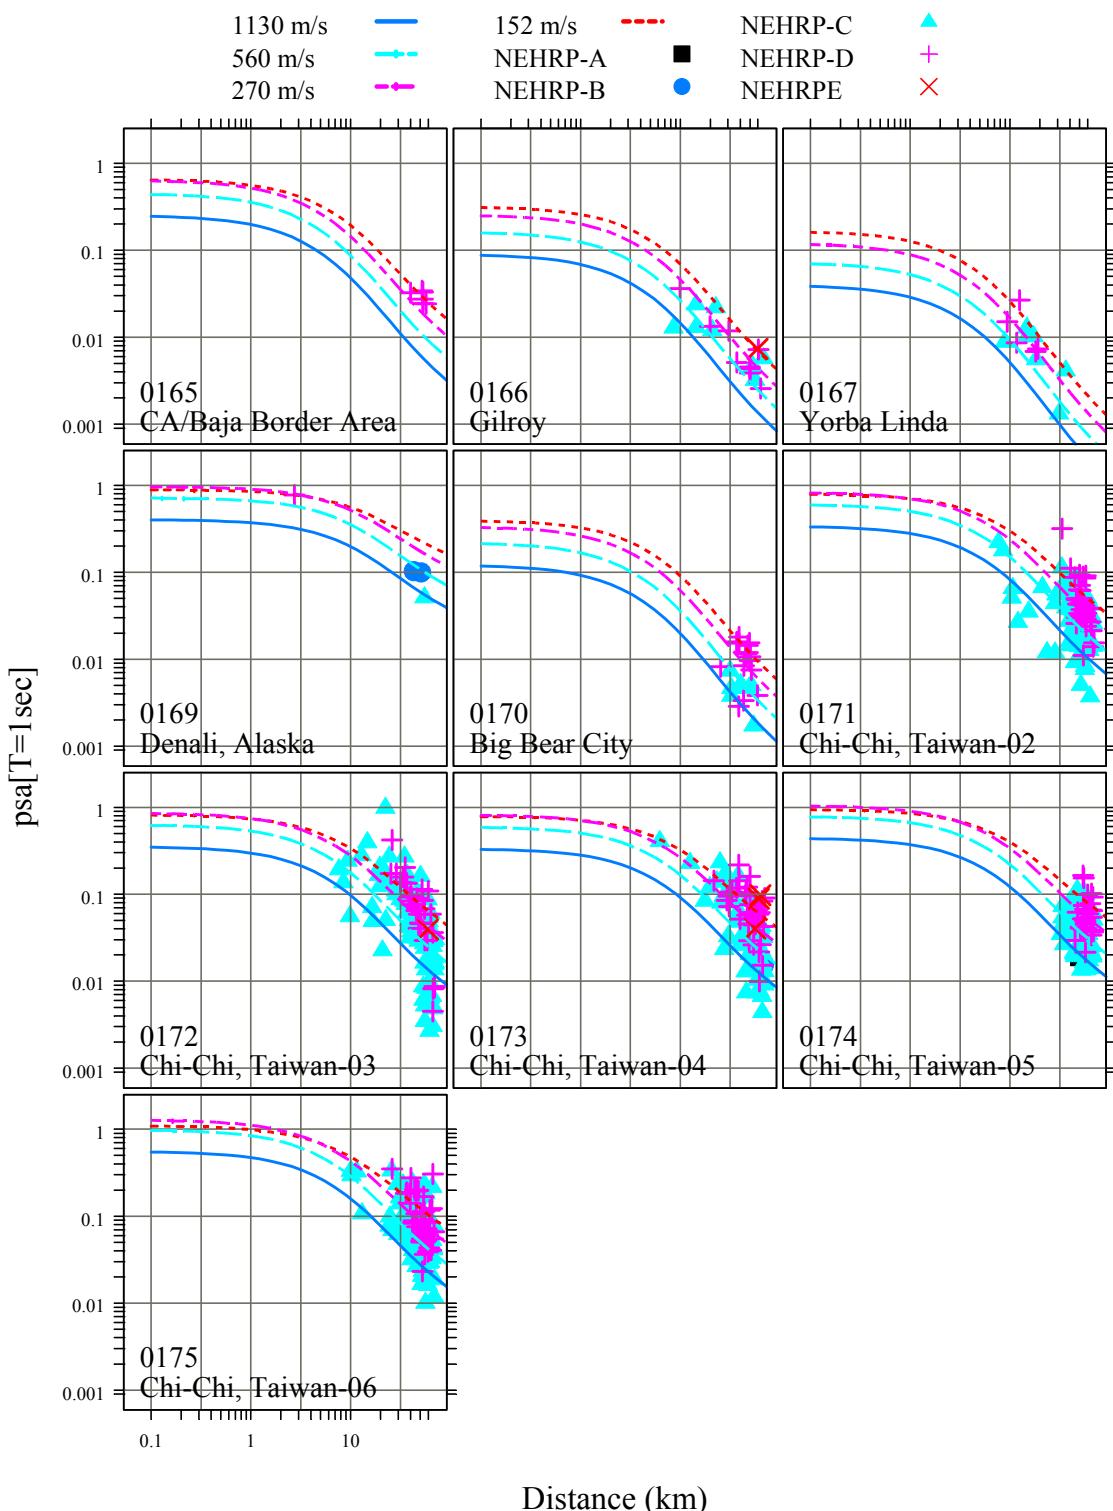

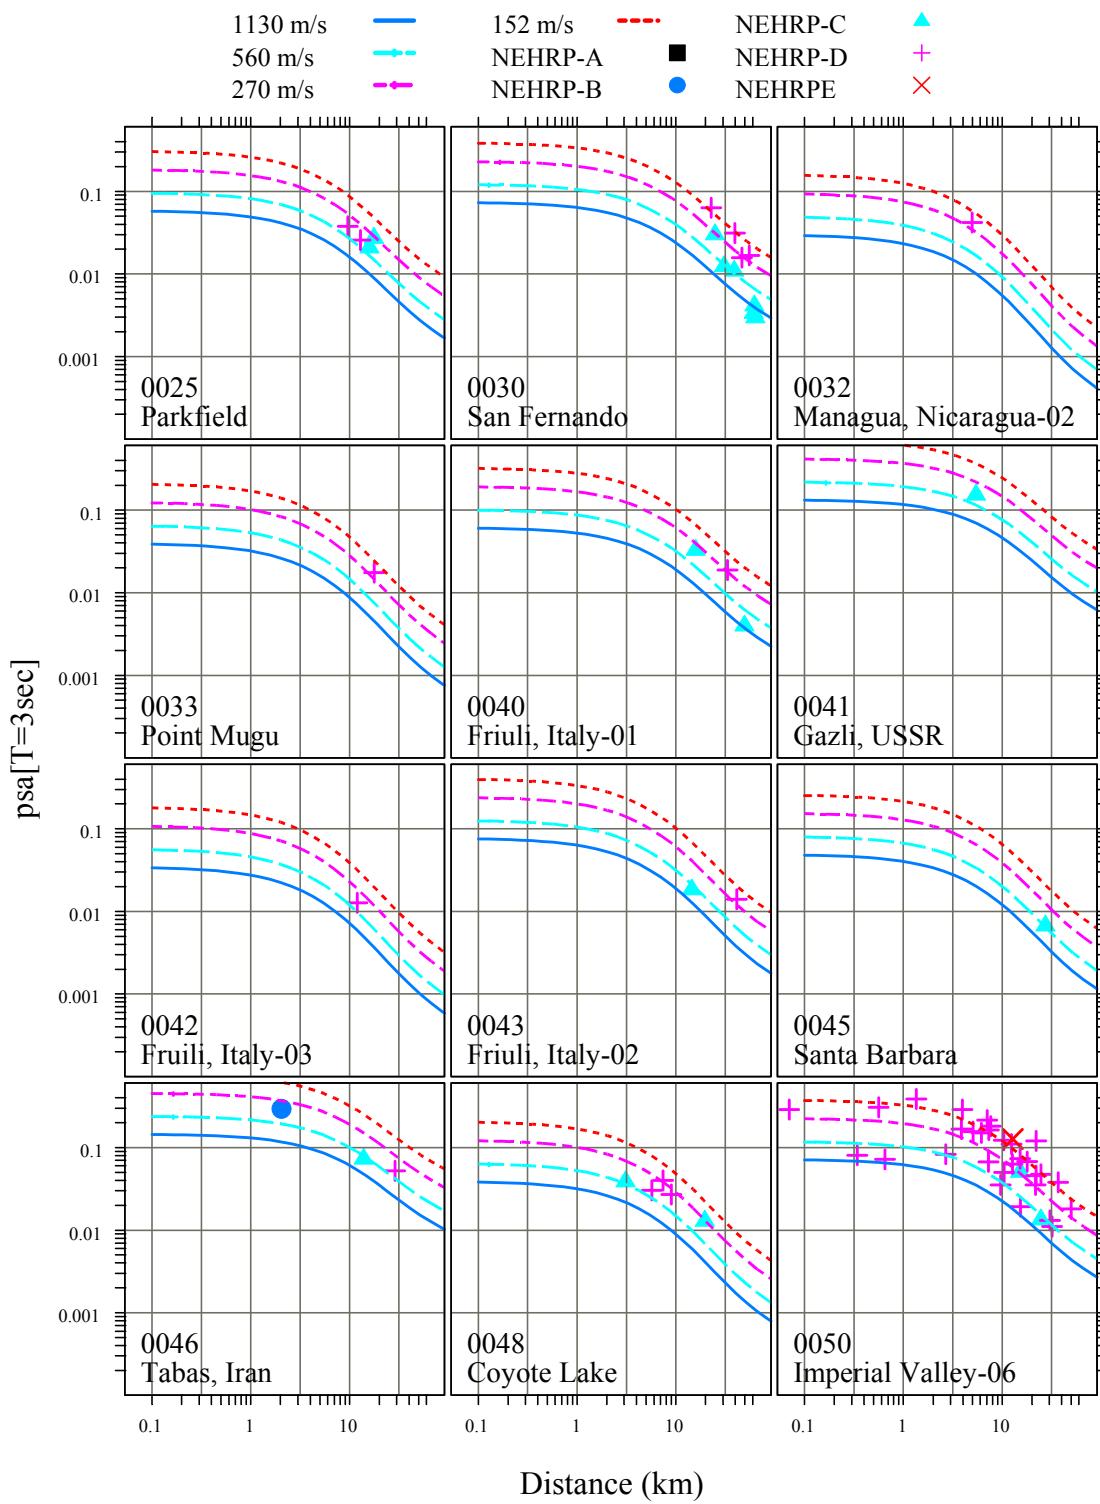

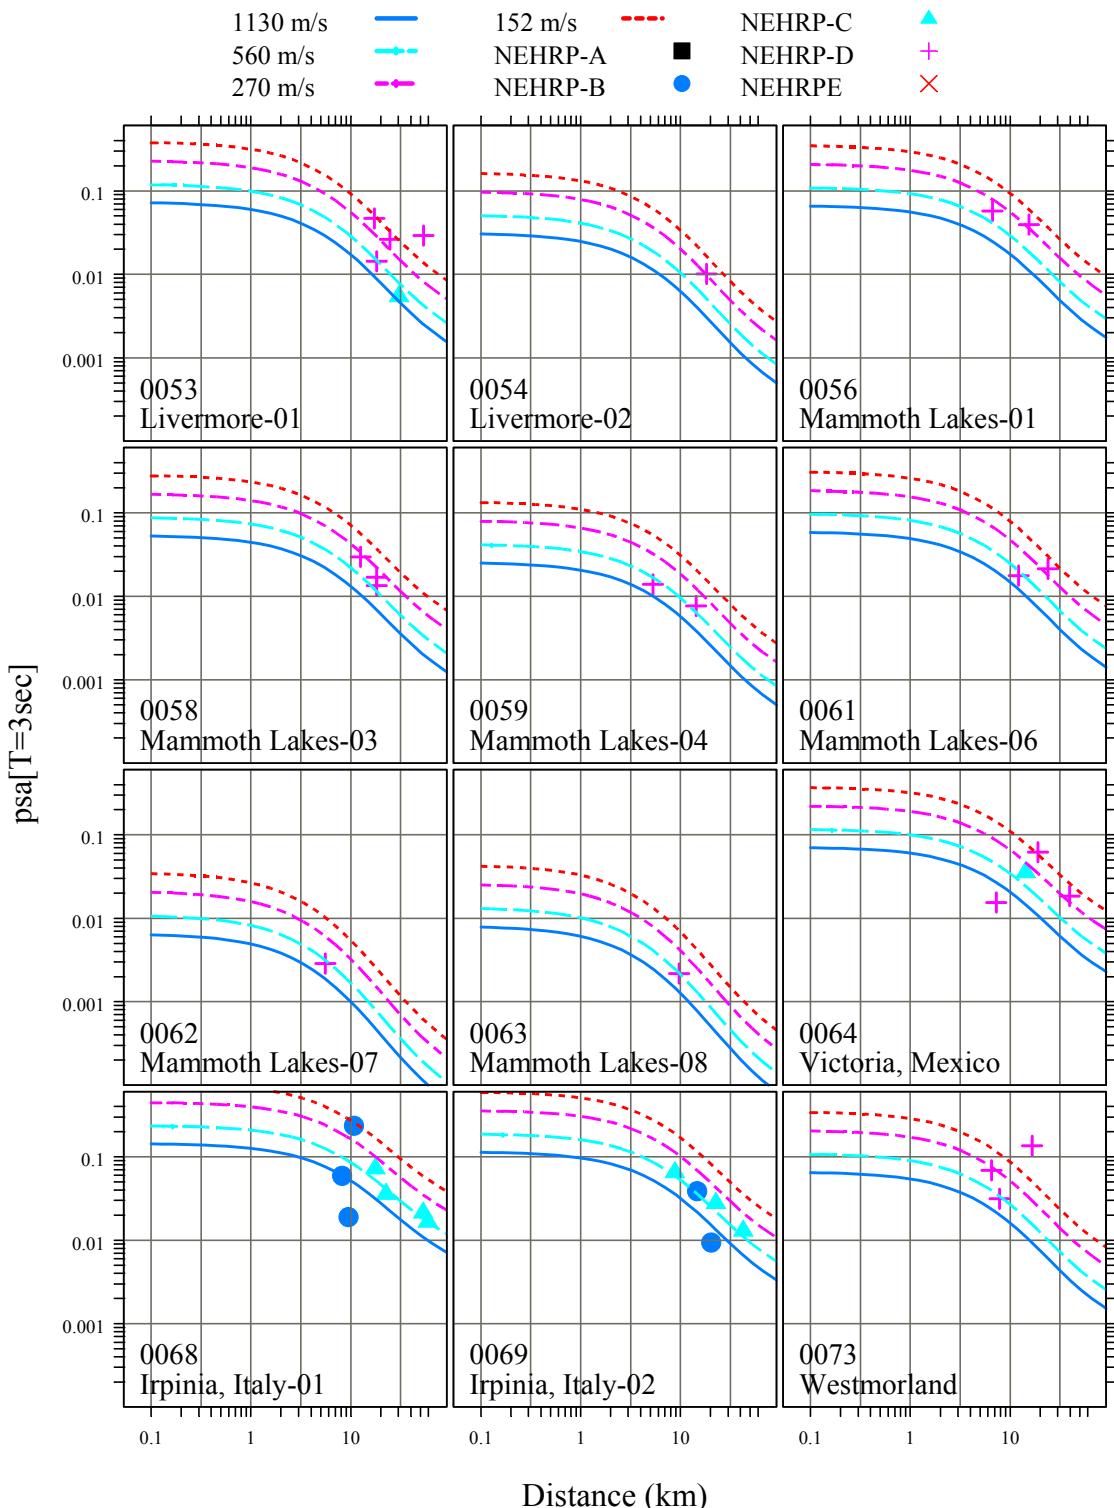

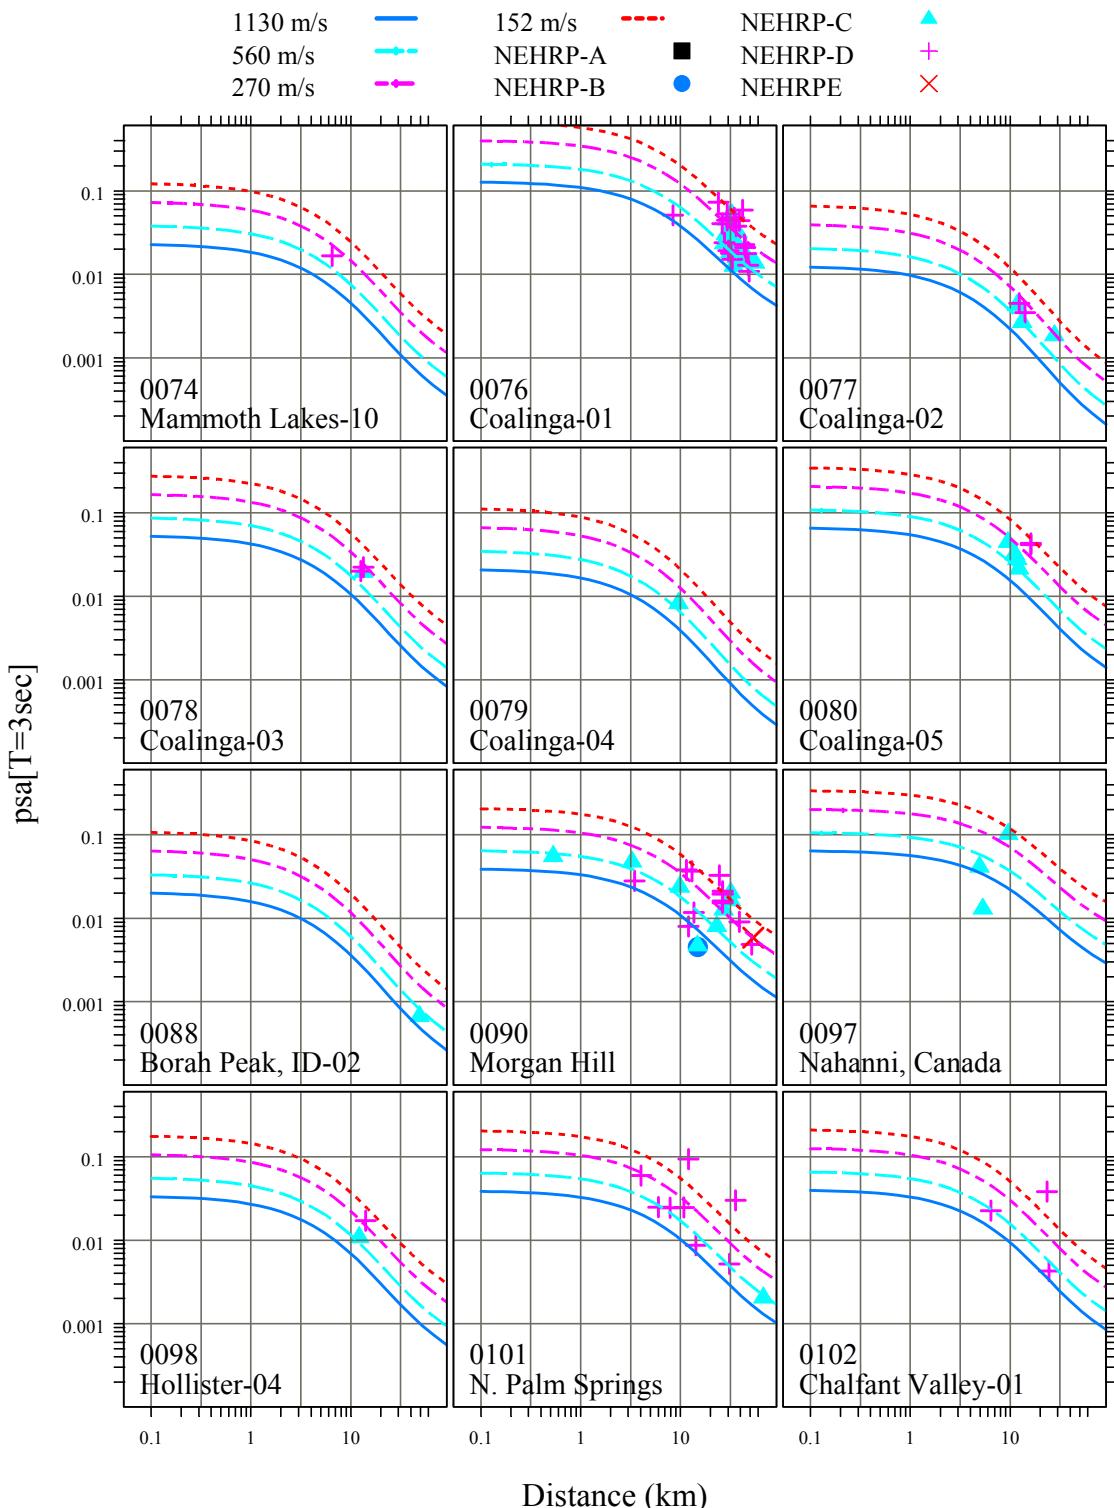

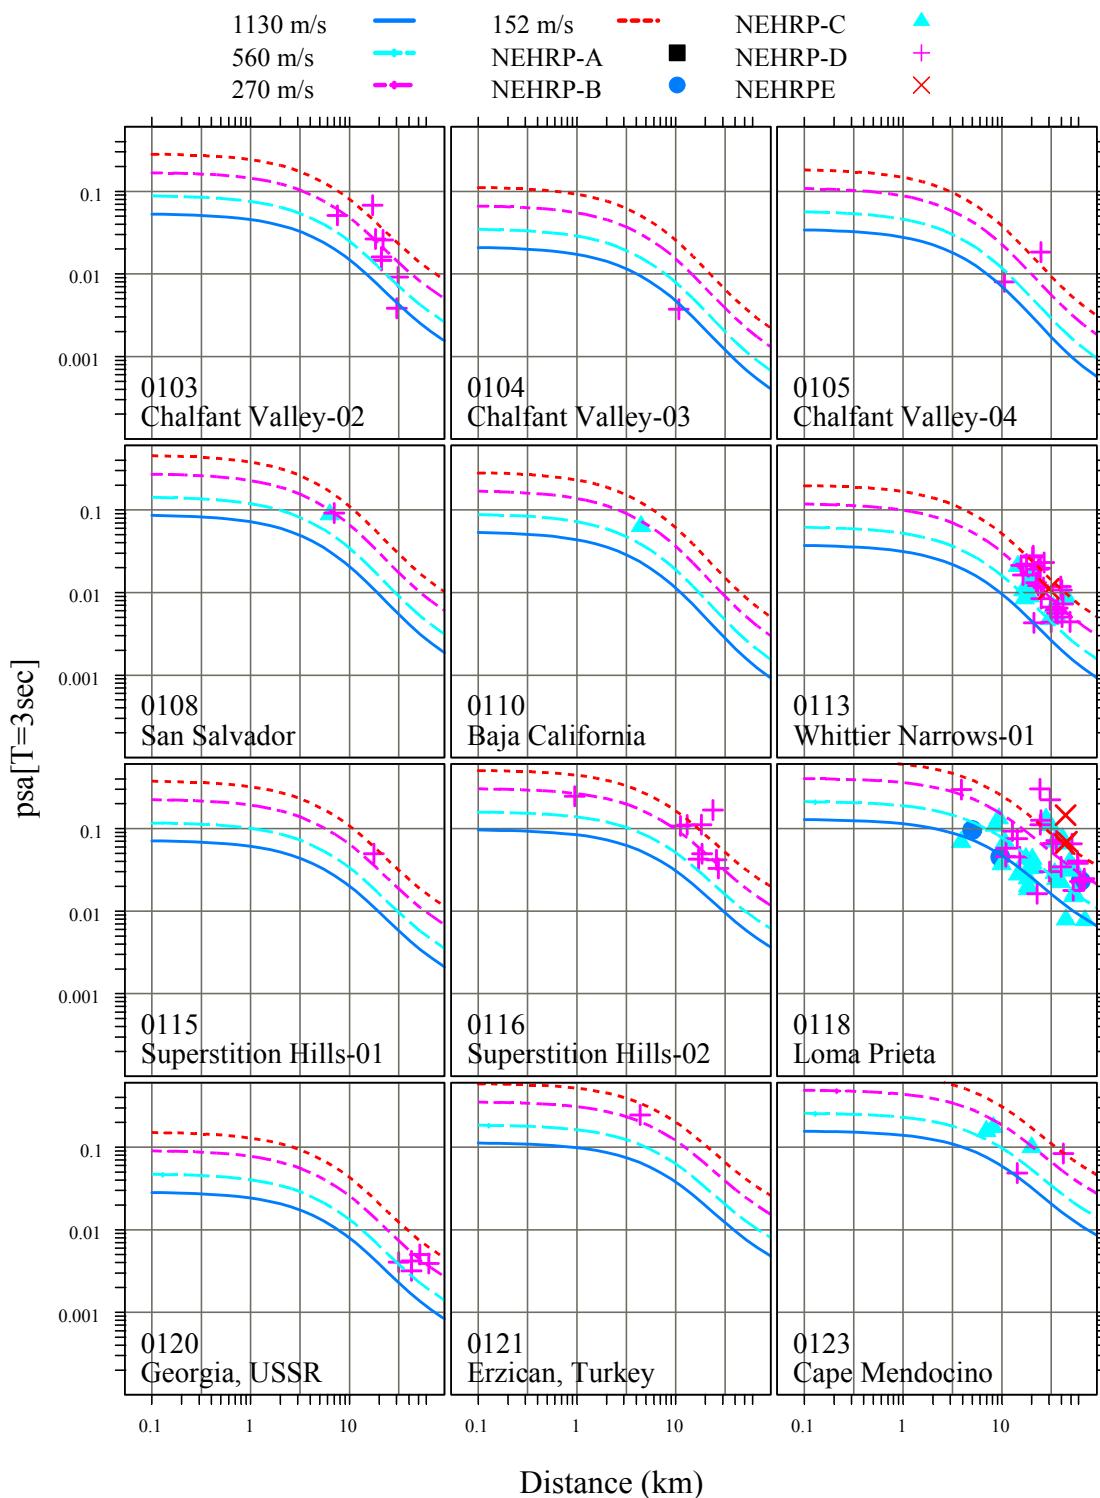

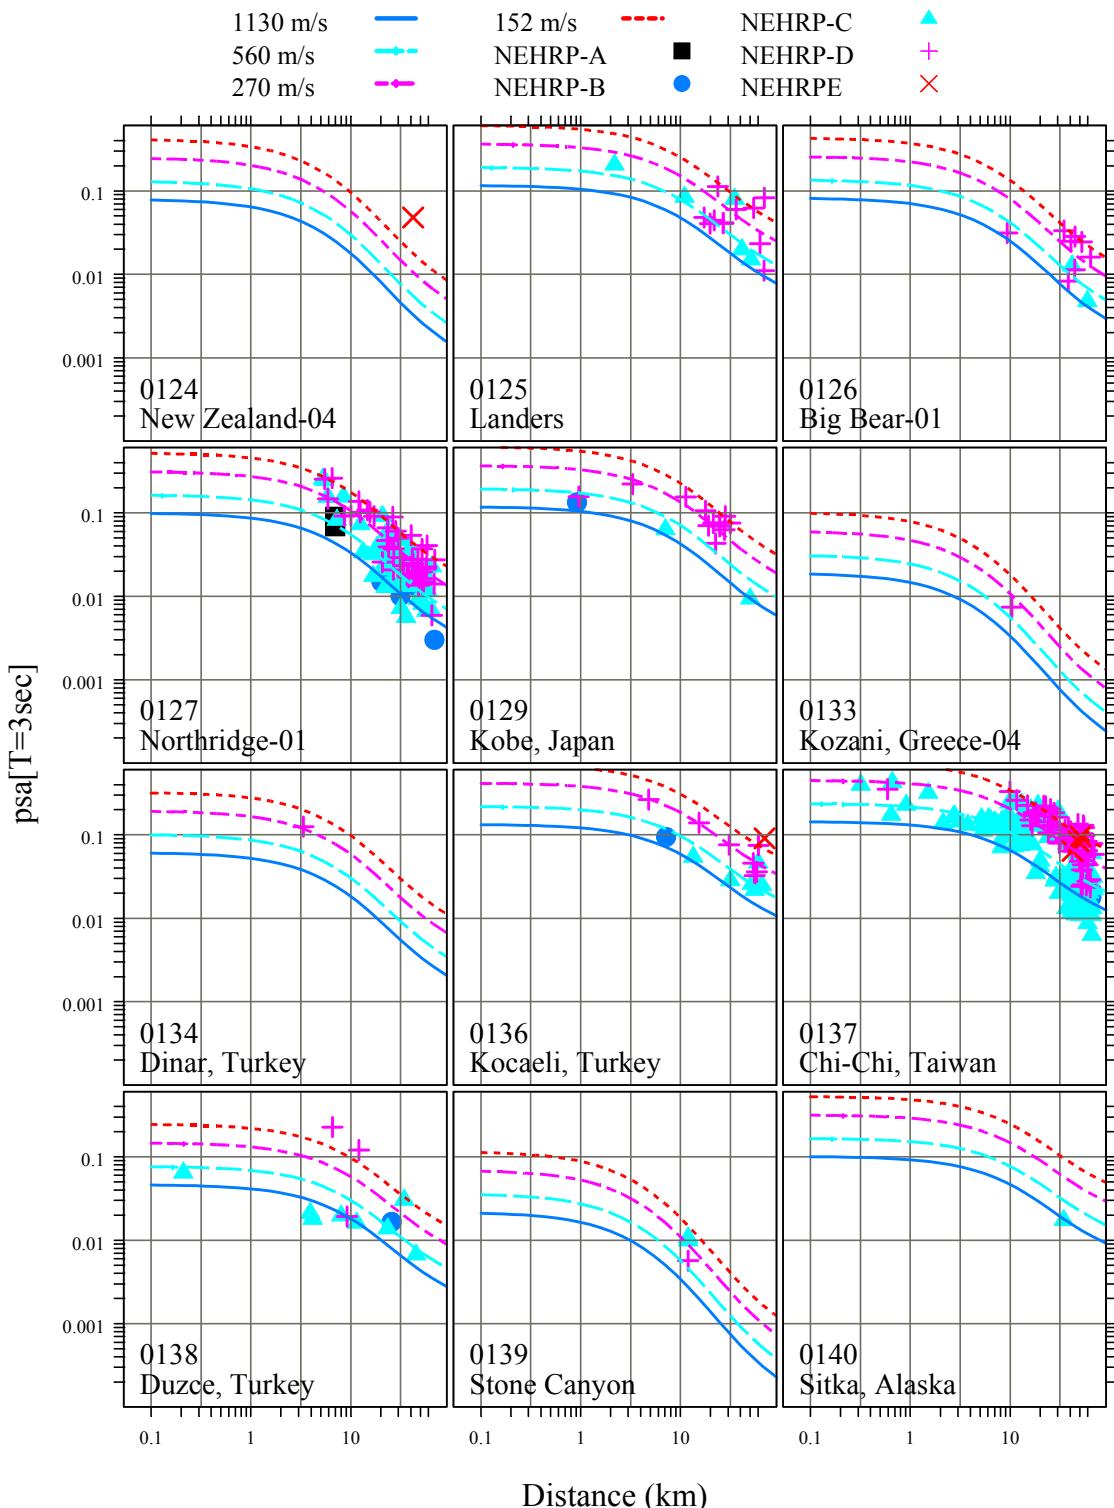

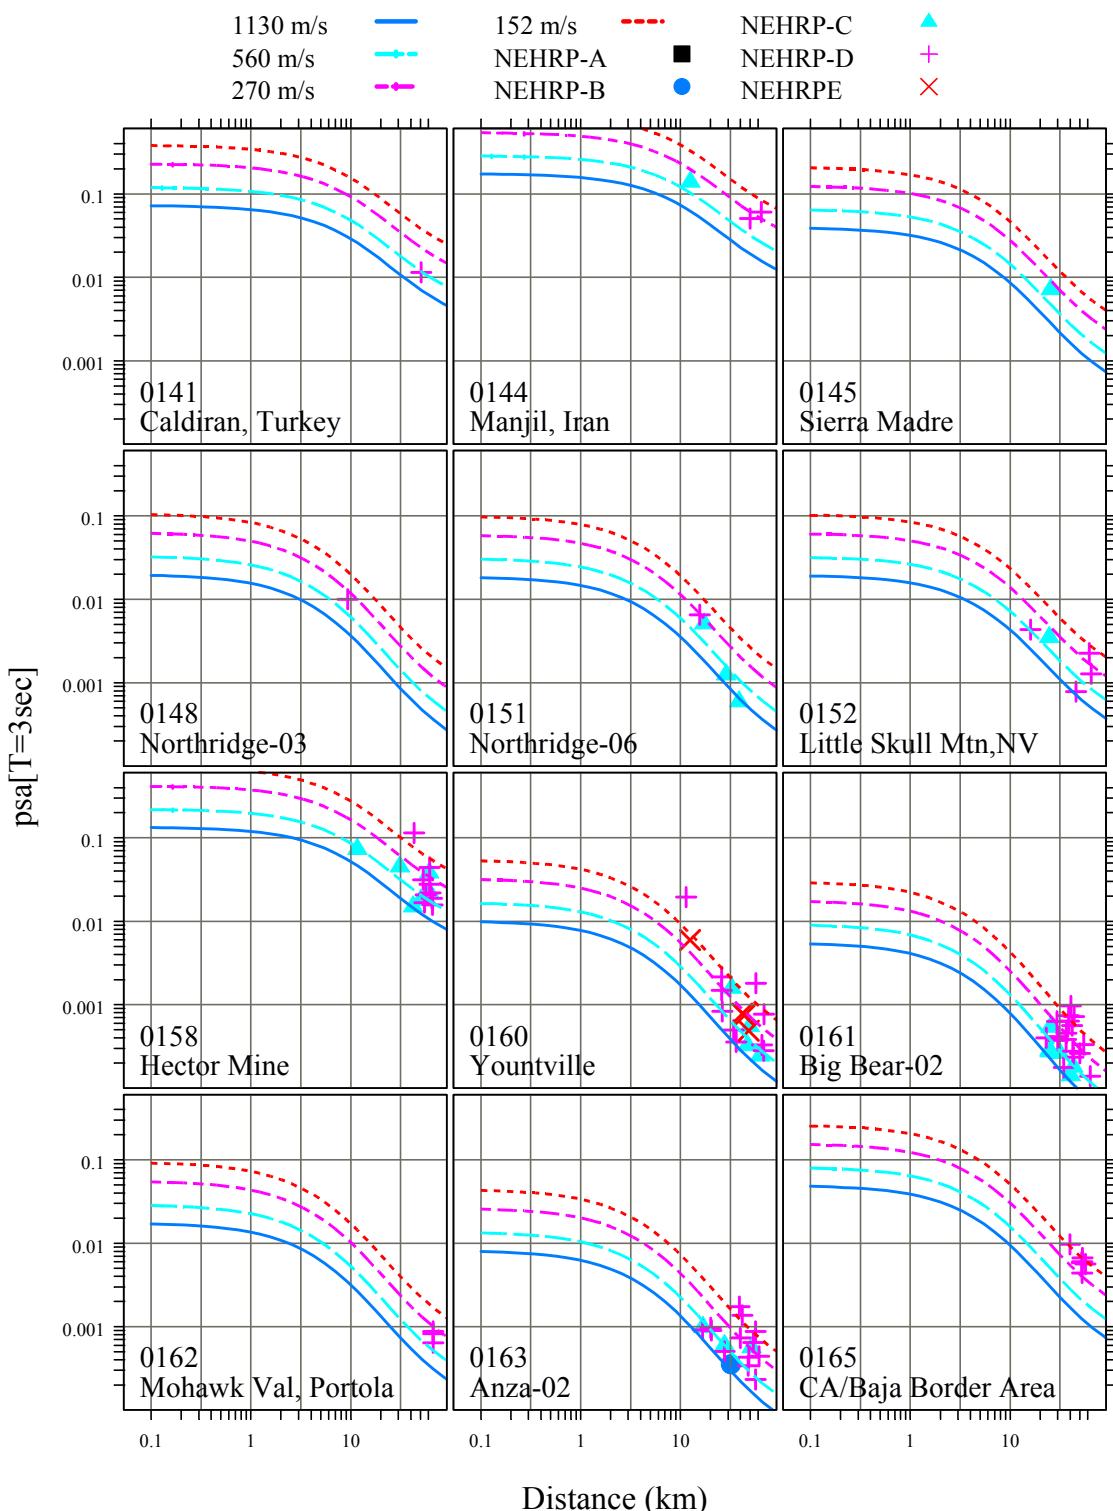

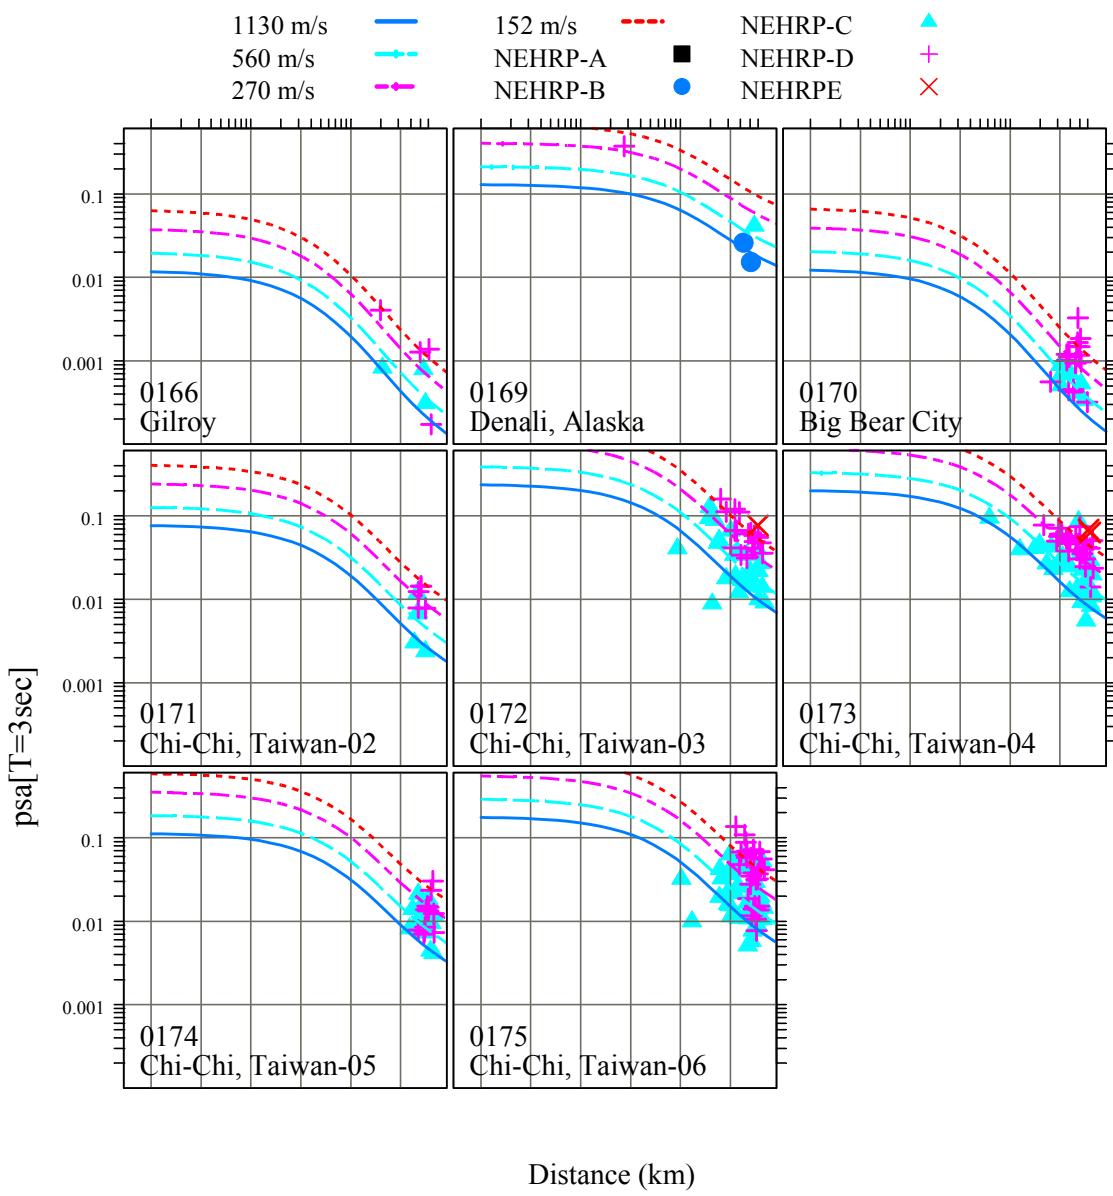

Appendix F: Model SAO2006—Update of Attenuation Model of Sadigh and Others (1997), Using PEER-NGA Dataset of Chiou and Youngs (2006)

INTRODUCTION

Comparisons of predicted median motions from CY2006⁴ to those from Sadigh and others (1997) (SAO97) are shown in Figures 39–44 of Chiou and Youngs (2006). It appears that there are substantial differences between the two models at $M > 5.5$, particularly for the rock conditions. The large differences are expected because SAO97 was developed more than 10 years ago with less reliable data⁵ and without the benefits of the ground motion research (particularly in the area of soil response) accomplished in the last 10 years. To allow for a more meaningful comparison with CY2006, SAO97 is updated to include the current NGA dataset and to implement a few modeling concepts that do not require changing SAO97's functional form. We'll focus on the model for rock condition because agreement between the rock models is worse than agreement between the soil models. This update is not aimed to provide a complete attenuation model that can be used in engineering practice. Rather, it is used only to understand the substantial difference in "rock" motion between CY2006 and SAO97.

We'll show that median predictions of the updated SAO97 model are no longer substantially different from those of CY2006. We attribute the good agreement to the improved fits of updated SAO97 to NGA data.

⁴ This appendix was written in 2006 using the preliminary model CY2006 and it has not been updated to the current model CY2008. However, the conclusions given in this appendix are not likely to be affected by the switch to CY2008.

⁵ For example, spectral shape data, instead of spectral acceleration data, were used in the development of SAO97. Also, the old site classification has undergone extensive revision and as a result some rock sites are re-classified as soil sites, and vice versa.

STRONG-MOTION DATASET AND THE EQUIVALENT V_{S30} FOR ROCK AND SOIL CONDITIONS

We use the same dataset that was selected and used by Chiou and Youngs (2006). The CY2006 dataset consists of 1087 data points from main shocks at distances less than 70 km. It's important to note that, although the recent large-magnitude data from Taiwan and Turkey are included in this dataset, the bulk of data still comes from California, as shown on Figure F.1a.

As SAO97, the updated attenuation model is developed for two general site conditions of soft rock and soil. The soft rock condition consists of Geomatrix site class A (very thin soil, < 5m, over rock) and B (shallow stiff soil, 5 to 20 m, over rock). The soil condition includes Geomatrix site class C and D (deep firm soil conditions). Site condition of each recording station is assigned according to the Geomatrix site code (C_3) given in the PEER-NGA database.

Summary statistics of V_{S30} for the rock and soil categories are listed in Table F.1 and the histograms are shown on Figures F.1b and F.1c. Because the weak-motion soil response in CY2006 is modeled by $\ln(V_{S30}/1130)$, we'll use the geometric mean of V_{S30} as the reference point for comparison with CY2006. The geometric mean is slightly different between pga and 1-sec PSA because their V_{S30} distributions are different due to the minimum usable frequency requirement. However, the difference is not large enough to make a difference and we'll use 500 m/sec as a compromise⁶.

We also want to point out that the V_{S30} distribution of California rock data is bimodal with a geometric mean of 485 m/sec, lower than the full-set value of 505 m/sec. The first mode of the rock V_{S30} data is similar to the geometric mean of soil V_{S30} data. One explanation of this observation is that many of these rock sites happen to be within geological units (such as Qal) where Geomatrix classification is ambiguous in the absence of reliable information on soil depth.

As in CY2006, footwall and hanging-wall sites are included in the regression analysis. Excluding FW/HW sites will impact the style of faulting effect for reverse event in a manner similar to that described in the “Modeling Steps” section of Chiou and Youngs (2006).

⁶ We used $V_{S30}=520$ m/sec as the point of comparison in Figures 39–44 of our main text. We'll update these figures to $V_{S30}=500$ m/sec when we revise the report in the future.

MODEL EQUATION:

To update SAO97, we combine the rock and soil model equations and use one random earthquake effect ($\tau \cdot z_i$) per earthquake. One could consult the paper by Sadigh and others (1997) to connect the new equation with the two original equations. The combined model equation is

$$\ln(y_{ij}) =$$

$$Z_r \left(C^r_1 + C^r_2 M_i + C^r_{2a} (M_i - 6.5, 0)_{\min} + C^r_3 (8.5 - M_i)^{2.5} + C^r_4 \ln \left(R_{rup_{ij}} + \exp \left(C^r_5 + C^r_6 M_i + C^r_{6a} (M_i - 6.5, 0)_{\min} \right) \right) \right)$$
$$+ Z_s \left(C^s_1 + C^s_2 M_i + C^s_3 (8.5 - M_i)^{2.5} + C^s_4 \ln \left(R_{rup_{ij}} + \exp \left(C^s_5 + C^s_6 M_i + C^s_{6a} (M_i - 6.5, 0)_{\min} \right) \right) \right)$$
$$+ C_{RV} Z_{RV}$$
$$+ \tau \cdot z_i + \sigma \cdot z_{ij}$$

where Z_r (the rock condition flag) is equal to 1 if site is on rock and 0 otherwise. Z_s (the soil condition flag) is equal to 1 if site is on soil and 0 otherwise. Z_{RV} (the reverse faulting flag) is equal to 1 if $30^\circ \leq \lambda \leq 150^\circ$ and 0 otherwise.

MODEL DEVELOPMENT:

Followings are descriptions of model development for pga and pseudo spectral acceleration at 1-sec period. Each model is developed in multiple steps. For convenience of reference, each step is labeled by affixing a lower case letter to “SAO2006.” (e.g., SAO2006.a, SAO2006.b, etc.).

Peak Ground Acceleration (Spectral Acceleration at Period of 0.01 Sec)

Step #1: SAO2006.a: Mixed-Effects Version of SAO97

In Step #1 all fixed-effects coefficients are set to the SAO97 values, except for coefficients C^r_1 , C^s_1 , and C_{RV} . The resulting coefficients C^r_1 and C^s_1 are nearly identical to those of SAO97 (probably not a coincidence). SAO2006.a is thus effectively the mixed-effects version of SAO97. Models SAO2006.a and SAO97 can be used interchangeably as far as predicting median pga goes.

The magnitude scaling of SAO2006.a (and SAO97) is appropriate for the NGA dataset (Fig. F.2a), therefore modifications of coefficients C^r_2 , C^r_{2a} , and C^s_2 are not necessary. This finding is consistent with the c_2 value in CY2006.

SAO2006.a also adequately models the distance attenuation of soil pga (Fig. F.2b). But, under-prediction of rock pga is noted at $R_{RUP} > 50$ km. A hint of overprediction of rock pga in the distance range of 5 and 15 km is also noted.

Median predictions from SAO2006.a are shown in Figure F.2c. There are substantial differences between SAO2006.a (SAO97) and CY2006. These discrepancies were also noted by Art Frankel (Comment #5 of his June-27-2006 list) in his review of the NGA model.

Step # 2 (SAO2006.b):

The lack of fits noted in Step #1 suggests that an increase (less negative in value) of coefficient C'_4 is needed. There is another (more) compelling reason to modify C'_4 . A large difference between C'_4 and C^s_4 , such as that seen in CY2006.a and SAO97, implies strong distance dependence in soil amplification even at large distances where soil response is linear and the soil amplification factor is expected to depend weakly on distance. To hamper the continuous increase of soil amplification with distance, we impose the equality constraint $C'_4 = C^s_4$ and modify coefficients C'_5 and C^s_5 to allow for nonlinear response at short distances. Furthermore, with the equality constraint, a large increase of C'_4 is expected and, consequently, the associated near-source magnitude scaling will be stronger than the scaling for near saturation as implied by SAO2006.a (and SAO1997). But a stronger near-fault magnitude scaling is not supported by the NGA dataset. On the contrary, in lights of the low motions recorded from the recent Turkey and Taiwan earthquakes, one could even make the case for negative near-fault magnitude scaling (i.e., oversaturation). We think allowing for oversaturation is a dramatic change in modeling concept and in engineering practice that its acceptance requires more careful studies. Therefore, we maintain the same near-fault magnitude saturation as SAO1997 by imposing $C'_6=1.1/ C'_4$ and $C^s_6=1.0/ C^s_4$. Changes to C'_6 and C^s_6 also trigger the needs to modify near-fault magnitude scaling for $M < 6.5$ (C'_{6a} and C^s_{6a}).

In summary, all coefficients except C'_2 and C^s_2 are modified in this step, with coefficients C^s_4 , C'_6 and C^s_6 being constrained by the conditions explained above. The resulting coefficients for soil model are close to the old values in SAO97, as expected. The new estimate of C'_4 is -1.6, close to the old soil value of -1.7 in SAO97. Thanks to the new coefficients, we notice better fits to data in the distance range of $5 \text{ km} \leq R_{RUP} \leq 15 \text{ km}$ and $R_{RUP} > 50 \text{ km}$ (Fig. F.3a). We also see a slight drop in intra-event standard error.

Median predictions from SAO2006.b are shown on Figure F.3b. Also shown on Figure F3.b are median predictions from CY2006 (solid lines). The discrepancies of rock predictions noted in the previous step and by Art Frankel are now much smaller. For $M = 6.5$, the magnitude mentioned in Art's comments, SAO2006.b and CY2006 are within 5% of each other.

Note that SAO2006.b still has problem with the near-fault prediction for $M = 5.5$ and smaller. This problem can be fixed by implementing a better magnitude scaling for lower M , such as the one used by CY2006. But we feel the analysis so far have already met the goals stated in the introduction. Therefore we will stop here and move on to the model development for 1-sec spectral acceleration.

Spectral Acceleration at Period of 1 Sec

Model development of the 1-sec spectral acceleration is similar in concept to that of pga , but the process is a lot simpler because the main update is related to magnitude scaling, which does not significantly affect other coefficients.

Step #1 (SAO2006.a; A Mixed-Effects Version of SAO97)

This is the first of a sequence of regression analysis. All fixed-effects coefficients are set to the SAO97 values, except for coefficients C^r_1 , C^s_1 , and C_{RV} . The resulting coefficients C^r_1 and C^s_1 are nearly identical to those of SAO97 (another coincidence?). SAO2006.a is effectively a mixed-effects version of SAO97. SAO2006.a and SAO97 can be used interchangeably as far as predicting median motion goes.

We notice a lack of fit in inter-event terms (Fig. F.4a), suggesting SAO97's magnitude scaling for spectral acceleration at 1-sec period needs to be revised. The predicted median rock motions differ from those of CY2006 by about 20% to 50% (Fig. F.4b). This large discrepancy is also noted and questioned by Art Frankel (2006) in his review of the NGA model.

Step #2 (SAO2006.b):

To improve the magnitude scaling, coefficients C^r_3 and C^s_3 are added to the list of free coefficients and the regression is repeated. The resulting inter-event terms are shown on Figure F.5a. The magnitude trend noted in Step #1 is not present. As a result, the inter-event standard error (τ) is about 16 % smaller than the value in previous step.

The predicted medina motion is shown on Figure F.5b. Discrepancy with CY2006 in the distance range of $10 \text{ km} \leq R_{RUP} \leq 50 \text{ km}$ and $\mathbf{M} \geq 5.5$ is now less than 5%. There are still large differences between the two models at $R_{RUP} < 10 \text{ km}$ and at $R_{RUP} > 70 \text{ km}$. Adjustment to coefficients C'_5 and C^s_5 is conducted next to improve the overall fits at $R_{RUP} < 10 \text{ km}$.

Step #3 (SA2006.c):

In this step, coefficients C'_5 and C^s_5 are added to the list of free coefficients. The resulting model significantly improves the fits at $R_{RUP} < 10 \text{ km}$ (Fig. F.6a). As a result, the agreement in median rock prediction (Fig. F.6b) is also much closer than the agreement achieved in previous steps.

CONCLUSIONS

We've shown that median predictions of the updated SAO97 model are not substantially different from those of CY2006. We attribute the good agreement to the improved fits of updated SAO97 to NGA data.

Appendix G: Response to Questions by U.S. Geological Survey (USGS) and California Geological Survey (CGS)⁷

⁷ USGS and CGS's comments were made with respect to a preliminary model developed in 2006 (Chiou and Youngs, 2006). However, we expect that our responses would also be valid with respect to the 2008 final model described in this report.

Art Frankel's Comment #1: Buried rupture versus surface rupture. Somerville and Pitarka (2006) find no significant difference in source terms, on average, between surface and buried ruptures for periods of 0.2 sec and shorter. Yet the NGA relations that do include terms for depth to top of rupture, predict significant differences between surface faulting and buried faulting at all periods. This discrepancy should be explained. It appears to me that the difference in surface and buried ruptures cited in Somerville and Pitarka (2006) may be at least partly due to the differences in the period of the forward directivity pulses. The buried ruptures used in their paper have magnitudes between 6.4 and 7.0, whereas the surface rupture events have magnitudes between 6.5 and 7.6 and produce forward directivity pulses with longer periods, on average.

RESPONSE FROM CHIOU AND YOUNGS

It is not clear whether Somerville and Pitarka intend to use their Figure 2 as an authoritative estimate of the difference in ground motion between surface and buried ruptures. They may merely use it as a compelling evidence of the existence of such difference.

We believe the ZTOR (depth to top of rupture) effects in the CY2006 model are consistent with the NGA mainshock data. Below, we present plots of earthquake terms from the CY2006 model with the ZTOR effect turned off to verify our claim. We'll also show that the ZTOR effect is responsible for a 15% to 20% reduction of the inter-event standard error (τ) at high frequencies. The large variance reduction highlights the importance of including ZTOR effort in the CY2006 model.

Earthquake Terms as a Function of Z_{TOR}

To obtain earthquake terms with the Z_{TOR} effect turned off, we take the CY2006 model, set coefficient c_7 (the coefficient of the Z_{TOR} term) to zero, and rerun the regression. The new earthquake terms, grouped into three magnitude bins, are plotted against Z_{TOR} on Figure 1. We use the pseudo-standard error $\sigma/\sqrt{n_i}$ ⁸ of each earthquake term as an approximation for estimation uncertainty. The red (long dashed) line is the predicted Z_{TOR} effect from the CY2006 model.

⁸ n_i is the number of records in an earthquake.

Figure 1 indicates a clear Z_{TOR} dependence in the earthquake terms, with some indication that the linear trend for earthquakes with $M \leq 5.5$ is weaker than that for earthquakes with $M > 5.5$. We tested the significance of magnitude dependence in the early stage of our model development and found it to be not statistically significant. We conducted the test against our final model again and also found the dependence to be not significant. Moreover, we cannot think of a physical basis for an increase in the Z_{TOR} effect with increasing magnitude. Based on these two reasons, we feel that we can't justify including magnitude dependence in Z_{TOR} effort in our model.

Is the CY2006 model inconsistent with Somerville and Pitarka (2006) at high frequency?

The average Z_{TOR} is 0.2 km for the 6 surface rupture events used by Somerville and Pitarka, and 3 km for the 4 buried rupture events. Note that Kobe earthquake was treated by Somerville and Pitarka as having a buried rupture, but its Z_{TOR} is 0.0 km. Using the CY2006 model, the expected difference between these two groups of earthquakes is about 0.15, not very different from the difference shown by Somerville and Pitarka⁹.

In fact, it's the depth effects at long periods that are quite different between the two studies. At 1-sec period, the difference between the two types of rupture is about 0.6 in Somerville and Pitarka, but only 0.12 is predicted by CY2006. To understand this striking difference, earthquake terms of 1-sec spectral acceleration is plotted on Figure 2. It turns out the 4 buried earthquakes picked by Somerville and Pitarka happen to have much larger event terms than other buried earthquakes with similar Z_{TOR} . The CY2006 model has a weaker depth effect because it was fit to all the earthquakes in the NGA dataset.

Reduction of Inter-Event Standard Error due to Z_{TOR}

As another confirmation of the importance of Z_{TOR} effect at high frequency, we compute the amount of reduction of the inter-event standard error due to including the Z_{TOR} effect. The results are shown on Figure 3 for every period in the CY2006 model. The reduction of inter-event

⁹ The average curve for shallow crustal earthquakes plotted on Figure 2 of Somerville and Pitarka may be in error. For example, at 0.1 sec period, the average of the 6 earthquake terms is more negative than what is indicated by the plotted curve.

standard error is large (by about 15% to 20%) at high frequency. It diminishes as the Z_{TOR} effect becomes smaller toward longer periods.

Future Refinement of the Z_{TOR} term

The recent paper by Shearer et al (2006) indicates that the stress drops of southern California earthquakes show an increase with increasing depth up to a depth of ~ 8 km, and no trend below this depth. In our model development, we did not find that a change in the slope of the depth trend at large depths was statistically significant. However, we have very limited data for $Z_{\text{TOR}} > 8$ km. Our data cannot reject the trends seen by Shearer et al (2006). Based on their results we plan to change the depth trend to level off at a depth of about 8 to 10 km. We will have this adjustment by the time of the meeting on the 25th.

Art Frankel's Comment #2: Too many predictive variables: *The above paragraph points out the danger of using too many predictive variables. For example, magnitude-dependent effects may be confused with a depth to top of faulting effect. Larger events are more likely to rupture the surface. Also, rupture aspect ratio is correlated with magnitude, so it is not obvious these two effects can be separated using the available data.*

CHIOU AND YOUNGS'S RESPONSE

Question of Confusing Magnitude-Dependent Effects with Z_{TOR} Effect

Our response to this question is already in the response to Frankel's Comment #1, in which we demonstrated that, given the magnitude scaling of Chiou and Youngs, there is a clear and significant effect of Z_{TOR} .

Too many predictors in the Chiou and Youngs's model?

We include in our model terms to address six basic trends in residuals: magnitude, distance (including magnitude effects), style of faulting, hanging wall, depth to top of rupture (addressed in our response to 1), and site condition effects. We believe that all of these trends are observed in the data and should be included in the model. Our formulation attempts to model these trends with smooth functions to avoid sharp "corners", rather than magnitude and distance ramps. This leads to somewhat complicated model equations, but not necessarily more parameters.

Frankel's Comment #3: Foot wall term. *Chang et al. (BSSA Dec. 2004) shows that there is a dip in residuals of the Chi-Chi footwall motions (at distances less than 15 km) when they are plotted as a function of nearest distance to rupture. This is caused by the fact that the distance to the center of the rupture is farther than the nearest distance for footwall sites. Is this relative dip of footwall ground motions accommodated in the functional forms used in NGA? If not, this could artificially lower ground motions in the distance ranges greater than 15 km. The dip in Chi Chi ground motions is also observed when using RJB. This dip does not appear to be present in the Northridge data. This calls into question the utility of the Chi Chi records for predicting ground motions for large events in other regions (see below).*

RESPONSE FROM CHIOU AND YOUNGS

We agree with Ken's comment; the dip in residuals of the footwall motions at distances less than 15km is an artifact resulting from not having a hanging wall term in Chang et al.'s equation. To verify this claim and to elaborate on the impact of hanging wall term on footwall residuals, we

take the same subset of Chi-Chi mainshock data used by Chang et al. and fit two equations to these data. The first equation $\ln y = a + b \ln(R_{RUP} + c)$ is identical in form to the equation used by Chang et al. The 2nd equation includes the hanging wall term developed by Chiou and Youngs (2006),

$$\begin{aligned}\ln y &= a + b \ln(R_{RUP} + c) \\ &+ d \cdot \cos^2 \delta_i \cdot \tanh\left(\frac{R_{RUPij}}{2}\right) \tan^{-1}\left(\frac{W_i \cos \delta_i}{2(Z_{TOri} + 1)}\right) \frac{1}{\pi/2} \left\{ 1 - \frac{R_{JBij}}{R_{RUPij} + 0.001} \right\}\end{aligned}$$

The resulting coefficients are listed in Table 1.

Median predictions from these two equations are shown on Figure 1. The hanging wall term has a large influence on parameter c because it stops the hanging wall data from pulling the distance curve upward. The larger c value in equation 2 results in lower motions at $R_{RUP} < 20$ km, and therefore the dip is no longer present in footwall residuals (Fig. 2).

We also want to add that the general form of our distance attenuation model was developed with HW data removed for all earthquakes (this was done only in phase 1 of our model development; see the “Modeling Steps” section of our report). That decision was motivated by findings similar to the above re-analysis of Chang et al. Removing the hanging wall data helps prevent them from biasing the distance scaling of near-source motions.

Table 1 Coefficients of Eqs. 1 and 2.

Equation	a	b	c	d	σ
1	3.776	-1.576	19.1	0	0.4123
2	3.926	-1.576	24.6	1.274	0.3097

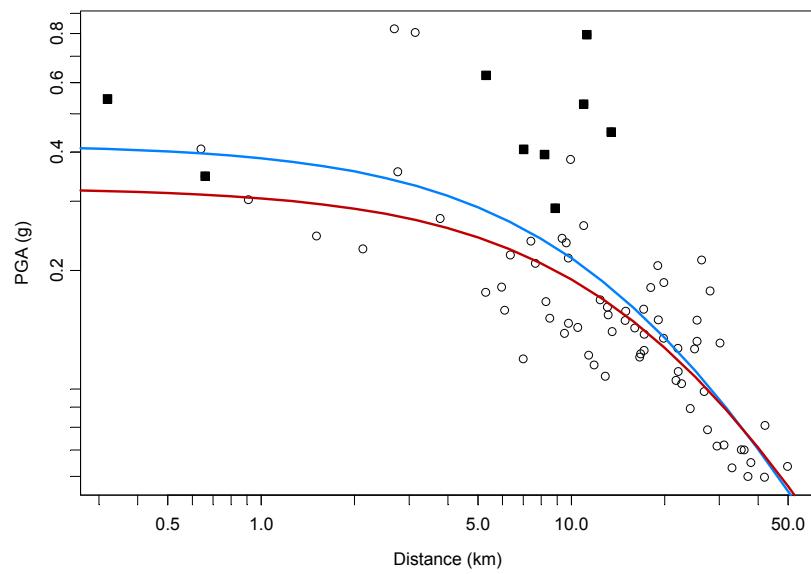

Fig. 1 Data and median predictions from equation 1 (blue) and equation 2 (red) for non-hanging wall sites. The hanging wall data are shown as solid squares.

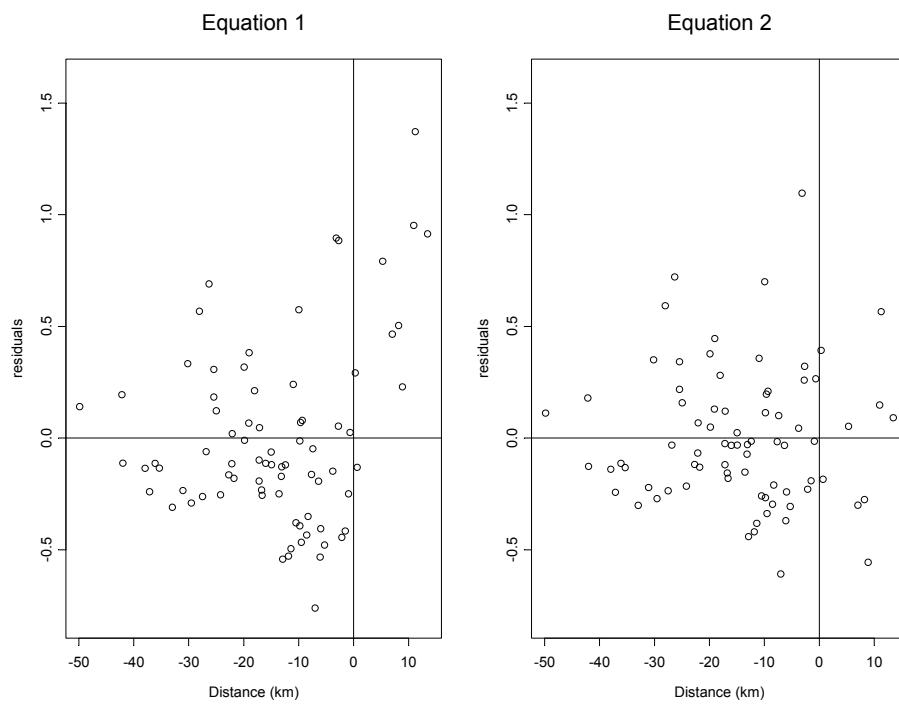

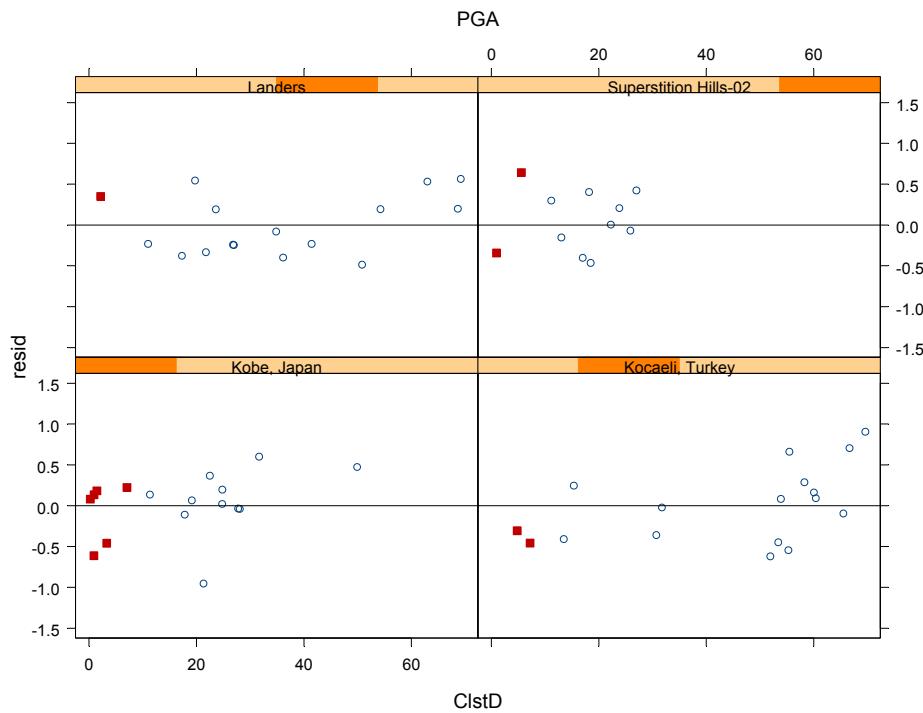

Fig. 2 Residuals from equations 1 and 2.

Art Frankel's Comment #4: Scaling with magnitude. For high frequencies ($\geq 5\text{hz}$), the spectral accelerations for close-in sites (< 10 km JB distance) are far higher for Superstition Hills, Landers, and Kobe earthquakes, than for the Kocaeli earthquake. Here I have chosen only strike-slip earthquakes. This suggests there are regional differences in stress drop for strike-slip earthquakes.

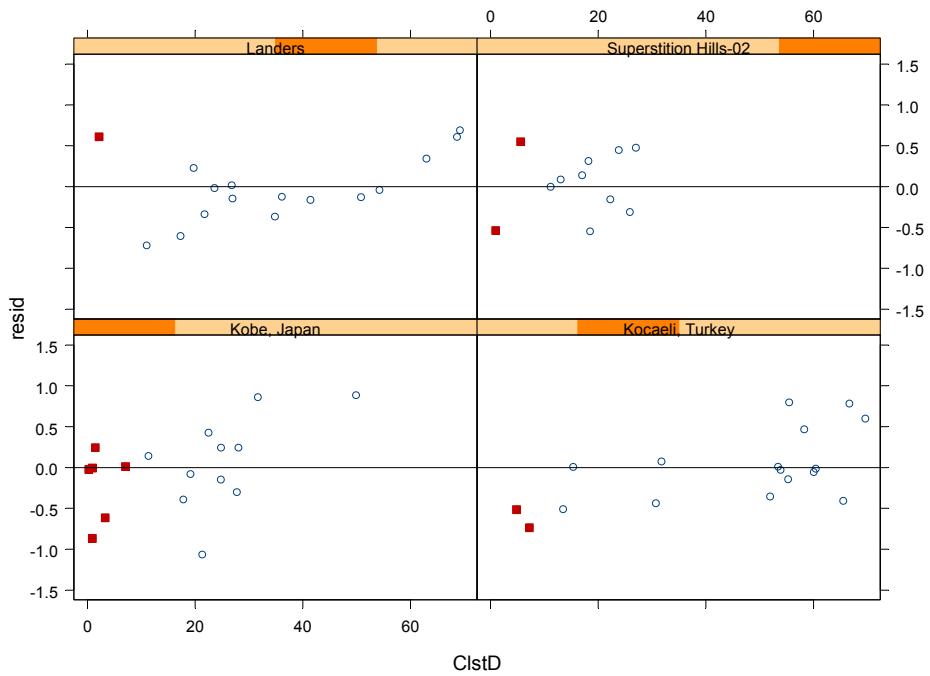

RESPONSE FROM CHIOU AND YOUNGS

We concur with Ken's comment that comparison of a few earthquakes is not really sufficient to derive general conclusion.

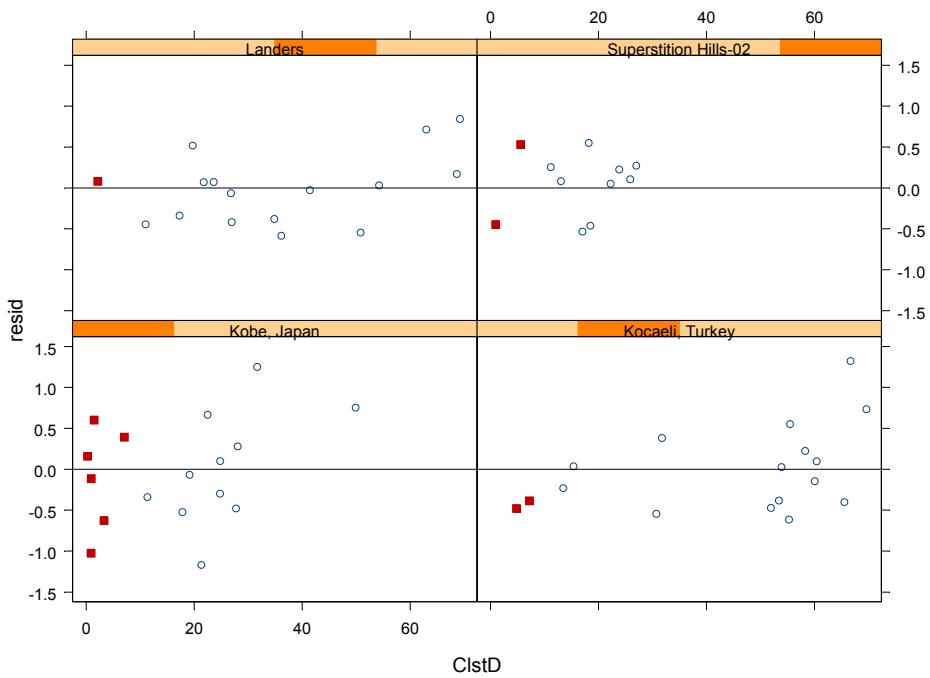

Following Ken's response, plots of intra-event residuals for these four earthquakes are provided below to allow checking of systematic bias or trend. Close-in sites with JB distance less than 10 km are plotted in red.

T=0.1 sec

T=0.2 sec

Art Frankel's comment #5: Changes from previous attenuation relations. *There are substantial differences in ground motions from moderate-sized ($M=6.5$) earthquakes at distances of 15-30 km between the NGA relations and the previous relations from the same authors (using the same site conditions). Since there doesn't appear to be very much new data in this magnitude and distance range, why the large differences? An egregious example is Boore-Atkinson (2006) compared to Boore, Joyner and Fumal (1996) for 1 sec S.A. for $RJB=0$ and $M=6.5$. There is about a factor of two decrease for BA (2006) compared to Boore et al. 1996. Why?*

RESPONSE FROM CHIOU AND YOUNGS

We believe the large differences noted by Art can be attributed to the lack of fit of the SAO97 model to the NGA dataset. After SAO97 is updated and the trend in residuals is removed, the median rock motion from the updated SAO97 model is not substantially different from CY2006's prediction. This is particularly true in the case of the 1-sec spectral acceleration. Details are given in Appendix F.

Art Frankel's Comment #7: Unique aspects of Chi Chi mainshock. *The fact that the Chi-Chi aftershocks do not show the same anomalously low high-frequency excitation in the near-source region (< 30 km) as the mainshock (Wang et al., Dec. 2004 BSSA) combined with the observation that regional and teleseismic spectra of the aftershocks and mainshock scale as expected for a constant stress drop model (Frankel, 2006, SSA annual meeting), indicates that there is a bias in the near-source recordings of the Chi-Chi earthquake. This may be due to the low accelerations near the north end of the rupture and/or footwall effects described above. We have previously noted the possible bias introduced by a higher number of stations located near the north end of the rupture compared to the south end. It is worth noting that Kanno et al. (June 2006 BSSA) exclude the Chi Chi mainshock data from their new attenuation relations for Japan (which include some California data), citing propagation differences between Taiwan and Japan. The Kanno et al. (2006) relations appear to be significantly higher than the NGA ones, for large magnitudes and close-in distances.*

RESPONSE FROM CHIOU AND YOUNGS

Are there propagation differences between Taiwan and California?

“Propagation differences” between Taiwan and Japan were speculated by Kanno et al. (2006), not demonstrated. In fact, based on the evidences described below, we believe differences in magnitude scaling and distance attenuation between Taiwan and California are not likely to be significant. First, we did not find significant difference in Chi-Chi mainshock’s γ (anelastic damping) once we account for truncation/incomplete data (Fig. 29 of our report is included). Second, we see similarity in pga attenuation (Fig. 1) between the model of Wu et al. (2001)¹⁰, which was derived from Taiwan data only, and the model of Chiou and Youngs (2006), which was derived mainly from California data. Finally, we also see similarity in magnitude scaling between the two models at $R_{RUP} > 50$ km and $M < 6.5$.

However, large differences do exist at $M > 6.5$ and $R_{RUP} < 20$ km, where the dataset of Wu et al. is poorly populated (Fig. 2). These differences shouldn’t be construed as proof of regional difference in near-source motions because the parameter (h) controlling the near-source prediction was fixed in Wu et al.¹¹, whereas the corresponding parameters (c_5 and c_6) in Chiou and Youngs were estimated from strong-motion data.

Unique Aspects of Chi-Chi Mainshock High-Frequency Motions and Their Effect on the Chiou-Youngs's Model

Several unique aspects of the Chi-Chi high-frequency motions were identified by the reviewers and they were also used by the reviewers to call into questions the utility of the Chi-Chi mainshock data for predicting ground motions of large magnitude event in California.

Some of the Chi-Chi motions are addressed in our responses to Mark’s question #1 and Art’s questions #3. To confirm and provide scientific explanations of the remaining issues would require additional ground motion data and more in-depth analysis. These studies may be of great

¹⁰ Wu, Y.M., T.C. Shin, and C.H. Chang (2001). Near real-time mapping of peak ground acceleration and peak ground velocity following a strong earthquake, *Bull. Seism. Soc. Am.* **91**, 1218 – 1228.

¹¹ The Wu et al. model is $\log_{10}(PGA) = 0.00215 + 0.581M_w - \log_{10}(R_{RUP} + h) - 0.00414R_{RUP}$. Parameter $h = 0.00871 \times 10^{0.5M_w}$ is fixed to the square root of the rupture area determined from a simple relationship between rupture area and M_w .

scientific interests, but from the standpoint of ground motion prediction the more relevant question to ask is: do the unique Chi-Chi data bias the estimates of key model parameters?

Throughout our model development we made an attempt to prevent any one earthquake from having a major effect on the estimates of model parameters. For example, we estimated the style of faulting effect with the Chi-Chi mainshock data removed. Another example, the general form of our distance attenuation model was developed with footwall (and hanging) data removed for all earthquakes so that the unique Chi-Chi footwall data will not affect these terms.

The outcome of this practice, we believe, is a model that is not unduly biased by the Chi-Chi data.

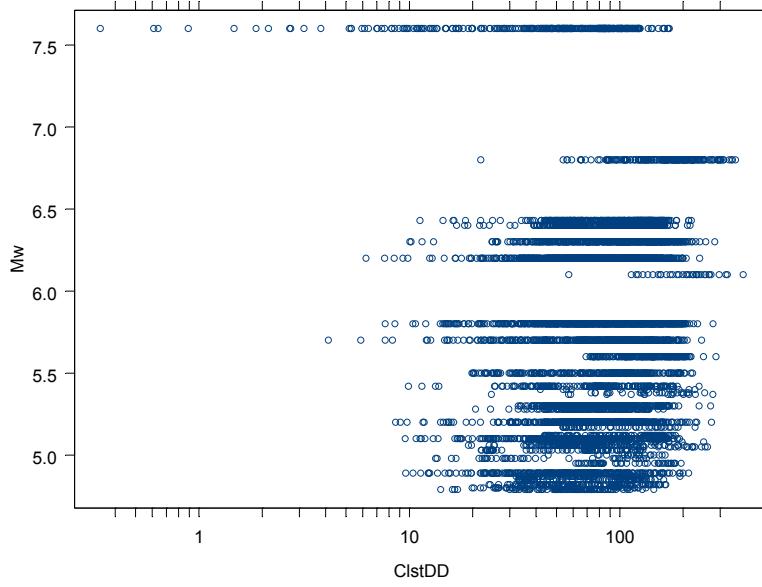

Fig. 2 Magnitude-distance distribution of dataset used in regression of pga model by Wu et al. (2001). Note regression dataset consists of pga data from 60 earthquakes recorded at 75 telemetered strong-motion stations in Taiwan, plus data recorded by TSMIP stations at distance less than 30km from source.

MARK PETERSEN'S QUESTION #1

Do you consider your ground motion prediction equations appropriate for seismic hazard assessments of California and throughout the western U.S.? Please explain. If you had left out international data and only used California data would you get a significantly different answer? Please explain.

Response to the Question of Applicability to California

This question arises from the concern about undue influence of non-California data on the regression results. A good way to address this concern is to examine the residuals of California only data. we'll show that significant trends can not be detected in California residuals. Thus, the NGA models are not biased relative to California data and the concern of undue influence of non-California data is not justified.

Before the residual plots are presented, we need to point out several important factors that work in favor of reaching an attenuation model that is California-like. First, the majority of the data selected for use in NGA model development is from California. As an example, the magnitude-distance-region distribution of data used in the Chiou and Youngs's model is shown in Figure 1. California data dominate the dataset at magnitude less than 7.2 and they play an important role in shaping the NGA model. Second, formulation of the NGA models and the constraints imposed on the model coefficients were mainly based on California data or on models derived from California data. For example, the Atkinson and Silva (1997, 2000) California-based seismic source models were used by Chiou and Youngs to generate synthetic motions, which were then used to formulate the form of magnitude scaling model. Another example is the use of California TriNet data by Boore and Atkinson and Chiou and Youngs to constrain the anelastic parameters. Thirdly, the developers were given the scope to develop models suitable for use in California. This goal strongly influenced developers' decisions and judgment made during model development.

Residuals plots for pga , T=0.2, 1 and 3 sec, are provided to facilitate the examination of model applicability to California in terms of magnitude scaling, distance attenuation, and site effect. In the following, we'll use plots from Chiou and Youngs to demonstrate the appropriateness of NGA model for California.

Inter-event errors are shown in Figure 2 and there is no significant bias relative to California earthquakes. In fact, the magnitude scaling model fits both the California and non-California earthquakes well except in the cases of pga and 0.2 sec the low values of several non-California earthquakes with $M \geq 7.2$. The magnitude scaling model was not dragged down to fit the low values. The non-California earthquakes do not have a major influence on magnitude scaling because it was constrained to follow an earthquake source model derived from largely California data. One might argue that the low values could still drag down the intercept C_1 (and hence the overall level of median motion). This will be addressed later.

Intra-event residuals in six magnitude bins are plotted against distance on Figure 2. Intra-event residuals plotted against $Vs30$ are shown on Figure 3. Fits to the California data are very good. It is difficult to argue there is significant bias relative to California data.

Based on the above observations, we conclude that, despite the use of some non-California earthquakes in the development of NGA models, the NGA models are appropriate for seismic hazard assessments of California.

Response to the Question of Applicability Throughout the Western U.S.

There are only a few data from the rest of western U.S. This makes it difficult to evaluate the applicability. Some developers warned that modifications of the NGA model may be needed in certain region. This applicability question is addressed in the Applicability Section of C&Y's report. Use of C&Y model in the rest of the WUS may require some modification if the anelastic attenuation (Q) is significantly different from California (e.g., in the Intermountain region).

Response to the Question of Using California Data Only

Given the good fits of C&Y model to California data, it is reasonable to state that if we were to develop a model using only California data the C & Y model would already be an excellent candidate. Some may suggest that the low values of several non-California earthquakes (Fig. 2) could still have a significant influence on coefficient C_1 and therefore C_1 should be re-estimated. Responding to this suggestion, we rerun the regression analysis using only California data with C_1 being the only free fixed-effect coefficient. The differences between the resulting C_1 and C&Y's C_1 are shown in Figure 5. The consequences of removing the non-California data are: an increase of C_1 (and hence the predicted median motion) by 5% to 10% at high frequencies

($T < 0.2$ sec), and a decrease of C_1 by less than 5% at long periods ($T > 3$ sec). Such changes are not considered to be significant.

MARK PETERSEN'S QUESTION #2

Do you feel that your equations have adequately accounted for epistemic and aleatory uncertainties to be used for public policy? Please explain. How do you suggest that the USGS account for the epistemic uncertainties in the ground motion relations in the national maps?

Preliminary Epistemic Uncertainty Model

The epistemic uncertainty in the median ground motions has a number of components, including:

- Uncertainty in selecting the appropriate database
- Uncertainty in selecting the appropriate model formulation
- Uncertainty in estimating the population mean with a finite data set
- Uncertainty in estimating the population mean due to uncertainty in the predictor variables in the dataset (magnitude, distance, V_{S30} , etc.)

The first two items are addressed (to some degree) by the alternative model forms and databases use by the five development teams. Presented below is an assessment of the uncertainty in the C&Y model due to the second two items.

Uncertainty in Estimation of Model from Finite Data Set

A simple first order estimate of the uncertainty in the median (mean log) estimates of ground motion for an individual model can be made using the standard statistical estimate of the uncertainty in the mean, \bar{x} , of a sample of size n :

$$\sigma_{\bar{x}} = \sqrt{\frac{\sigma_x^2}{n}} \quad (1)$$

where σ_x^2 is the sample variance.

The parameters of the PEER-NGA ground motion models are defined by mixed effects regression (or equivalently two-stage regression) such that the total variance in the log of ground motion amplitude is partitioned into an inter-event component τ^2 and an intra-event component σ^2 . For this case, an equivalent form of Equation (1) is

$$\sigma_{\ln[PGA]} = \sqrt{\frac{\tau^2}{n_{Eq}} + \frac{\sigma^2}{n_{Sites}}} \quad (2)$$

where n_{Eq} is the number of earthquakes and n_{Sites} is the number of recordings. Equation (2) can be used to qualitatively assess the estimation uncertainty in ground motion for different magnitude and distance intervals.

Figure 1 shows the magnitude-distance distribution of the data used to develop the C&Y model. The magnitude range was divided into four intervals, $M < 5$, $5 \leq M < 6$, $6 \leq M < 7$, and $M \geq 7$ and the distance range was divided into three intervals, $R_{RUP} < 10$, $10 \leq R_{RUP} < 30$, and $R_{RUP} \geq 30$. Table 1 lists the values of n_{Eq} and n_{Sites} for the C&Y data set and values of $\sigma_{\ln[PGA(m,r)]}$ computed using $\tau = 0.288$ and $\sigma = 0.515$.

Table 1 Application of equation (2) to C&Y dataset.

M and R_{RUP} Range	Average M	Median R_{RUP}	n_{Eq}	n_{Sites}	$\sigma_{\ln[PGA(m,r)]}$
$M < 5$ $R_{RUP} < 10$	4.7	7.3	6	25	0.156
$M < 5$ $10 \leq R_{RUP} < 30$	4.7	15.7	12	47	0.112
$M < 5$ $R_{RUP} \geq 30$	4.8	45.4	5	98	0.139
$5 \leq M < 6$ $R_{RUP} < 10$	5.6	7.0	23	32	0.109
$5 \leq M < 6$ $10 \leq R_{RUP} < 30$	5.5	16.9	50	263	0.052
$5 \leq M < 6$ $R_{RUP} \geq 30$	5.7	46.5	26	241	0.065
$6 \leq M < 7$ $R_{RUP} < 10$	6.5	4.4	24	78	0.083
$6 \leq M < 7$ $10 \leq R_{RUP} < 30$	6.5	20.1	26	210	0.067
$6 \leq M < 7$ $R_{RUP} \geq 30$	6.3	48.8	23	670	0.063
$M \geq 7$ $R_{RUP} < 10$	7.5	4.1	7	45	0.133
$M \geq 7$ $10 \leq R_{RUP} < 30$	7.5	17.9	8	71	0.119
$M \geq 7$ $R_{RUP} \geq 30$	7.5	50.3	10	170	0.099

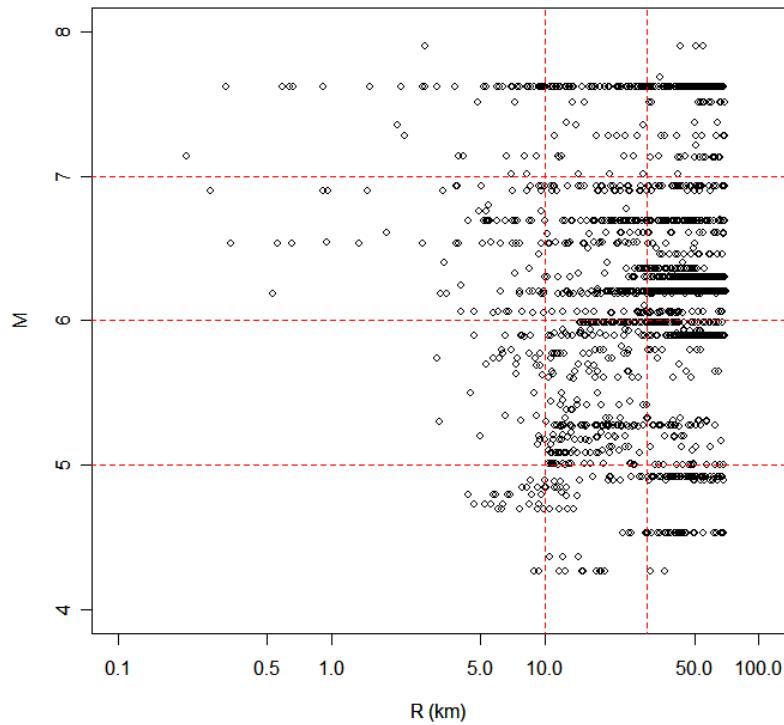

Fig. 1 Magnitude-distance distribution of C&Y dataset for pga.

The magnitude and distance ranges selected above are arbitrary but they provide an indication of the variation of uncertainty in the estimate of $\ln[PGA(m,r)]$ as a function the amount of data.

The uncertainty estimates illustrated above do not incorporate the structure of the regression model and any external constraints imposed in the fitting. For linear regression models there are standard formulations for the uncertainty in the mean estimate as a function of the location of the estimation point with respect to the mean of the predictor variables. The uncertainty is smallest near the mean of the predictors and grows as the estimation point moves to the edges of the data used to fit the model. For non-linear, mixed effect regression models, explicit formulation of the uncertainty becomes much more difficult.

An alternative is to use non-parametric methods to estimate the uncertainty in the median prediction. One method that is widely employed is the bootstrap (Efron and Tibshirana, 1993). In the standard bootstrap, repeated random samples of size n_{Total} are drawn with replacement from the original data set. Each bootstrap sample is fit and the resulting model used to estimate $\ln[PGA(m,r)]$ for a range of magnitudes and distances. The process is repeated multiple times and the resulting variability in $\ln[PGA(m,r)]$ provides an estimate of uncertainty. The bootstrap process draws repeated samples from the unknown true distribution of the data using the empirical distribution as a substitute.

Unfortunately, application of the bootstrap to a mixed effects regression model is not straight forward because of the assumed nested nature of the data (correlation of ground motions from the same earthquake) and there is very little in the literature on how to proceed. As a first step, bootstrapping of the intra-event data was performed. This involved sampling with replacement from the recordings for each earthquake to build a data set of the same size as the original. Figures 2 and 3 show the resulting range and 90% interval in $\ln[PGA(m,r)]$ for 100 bootstrap samples. It should be noted that Efron and Tibshirani (1993) recommend on the order of 1000 samples for confidence intervals. However, the results presented in Figures 2 and 3 indicate the magnitude of the estimation uncertainty for $\ln[PGA(m,r)]$.

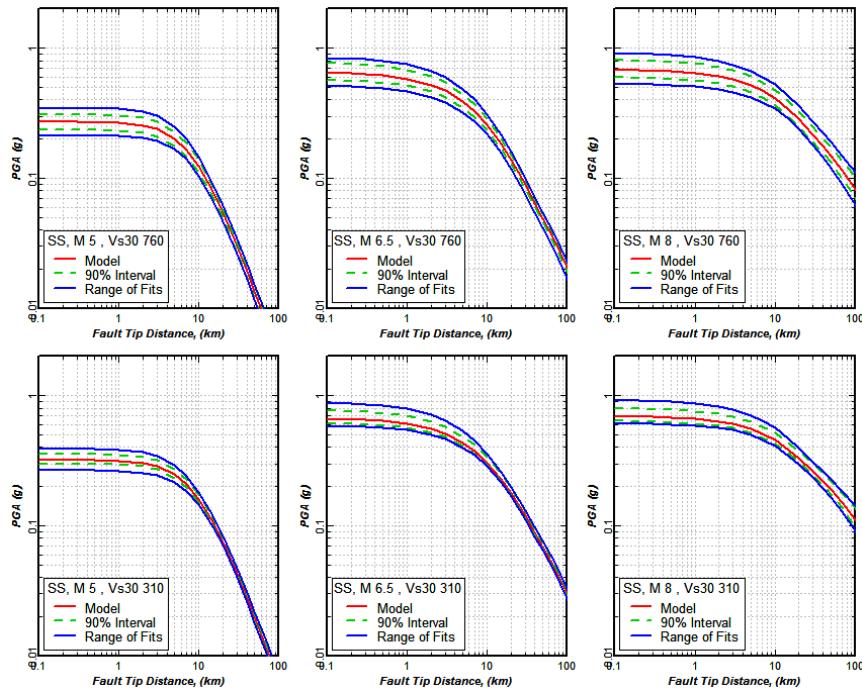

Fig. 2 Bootstrap 90% intervals for $\ln[PGA(m,r)]$ for strike-slip earthquake ground motions. Bootstrapping restricted to intra-event samples. ($Z_{TOR} = 5, 0, 0$; dip = 90°)

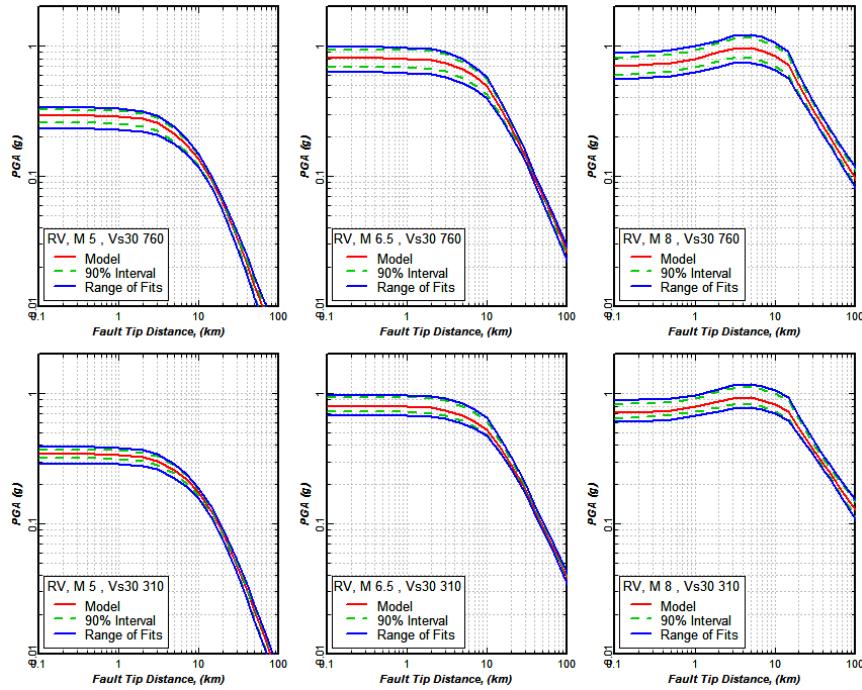

Fig. 3 Bootstrap 90% intervals for $\ln[PGA(m,r)]$ for reverse earthquake ground motions. Bootstrapping restricted to intra-event samples. ($Z_{TOR} = 5, 2, 0$; dip = 45° ; widths 3, 15, 21.21 km)

The examples presented above provide an estimate of uncertainty by sampling from the empirical distribution of the intra-event terms. An estimate of uncertainty from sampling from the inter-event terms can be provided by employing another non-parametric technique, the jackknife. The standard jackknife technique uses repeated samples in which one data point is left out each time. For a data set of size n , n samples are created leaving out each data point in turn. We adapted this concept by creating 125 data sets for the C&Y model, each set has one of the 125 earthquakes removed. Figures 4 and 5 show the resulting range of values for $\overline{\ln[PGA(m,r)]}$. Ninety percent of the estimates lie very close to the model prediction and the 90% interval is not shown.

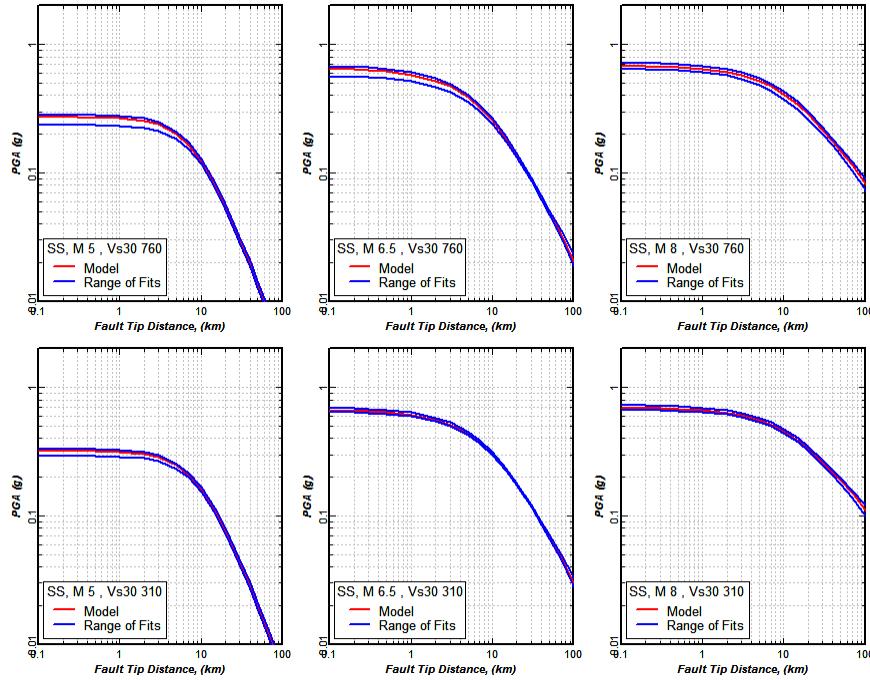

Fig. 4 Range of $\overline{\ln[PGA(m,r)]}$ for strike-slip faulting from jackknife (on earthquakes) fits to C&Y database ($Z_{TOR} = 5, 0, 0$; dip = 90°)

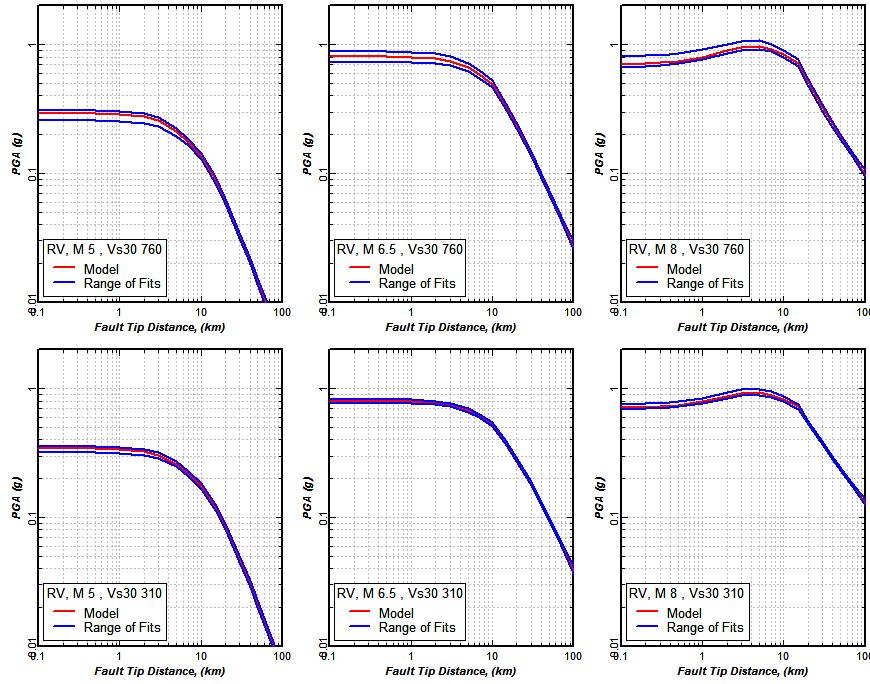

Fig. 5 Range of $\overline{\ln[PGA(m,r)]}$ for reverse faulting from jack knife (on earthquakes) fits to C&Y database ($Z_{TOR} = 5, 2, 0$; dip = 45° ; widths 3, 15, 21.21 km).

We believe that some combination of the uncertainties shown on Figures 2 and 3 with that shown on Figures 4 and 5 provides a reasonable estimate of the uncertainty in $\overline{\ln[PGA(m,r)]}$ derived from fitting the ground motion model to the selected data base.

Effect of Uncertainty in Predictor Variables

The fourth contribution to uncertainty in $\overline{\ln[PGA(m,r)]}$ is from uncertainty in the predictor variables (\mathbf{M} , R , Z_{TOR} , V_{S30}). We estimate this using simulation. One hundred data sets are simulated with random errors added to the predictor variables. The standard deviations for the individual values of \mathbf{M} and V_{S30} given in the flat file were used for these variables. Approximate errors for R and Z_{TOR} were included based on judgment (these will need to be refined). Figures 6 and 7 show the resulting uncertainties in $\overline{\ln[PGA(m,r)]}$.

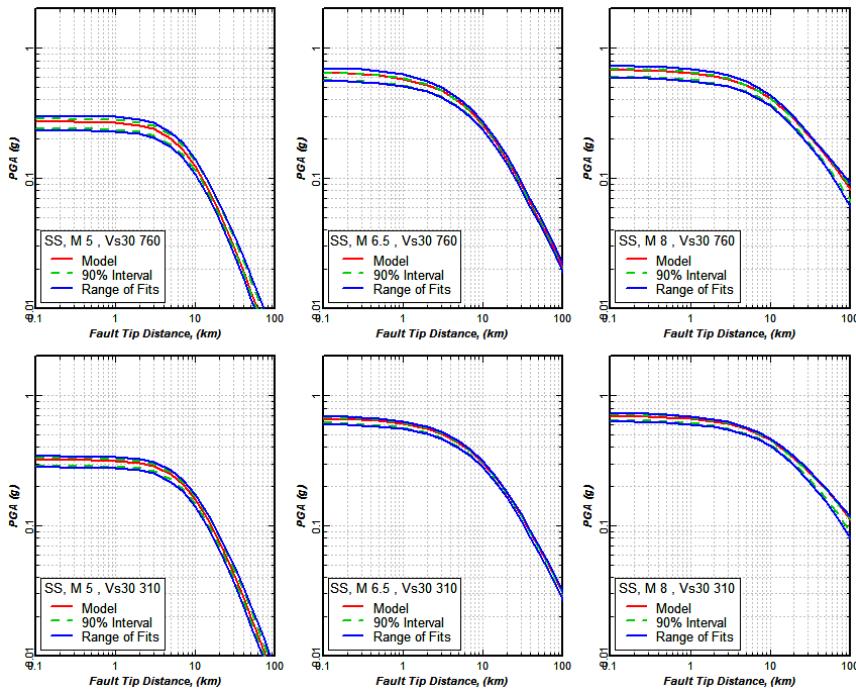

Fig. 6 Uncertainty in $\overline{\ln[PGA(m,r)]}$ for strike-slip earthquake ground motions due to uncertainty in predictor variables.

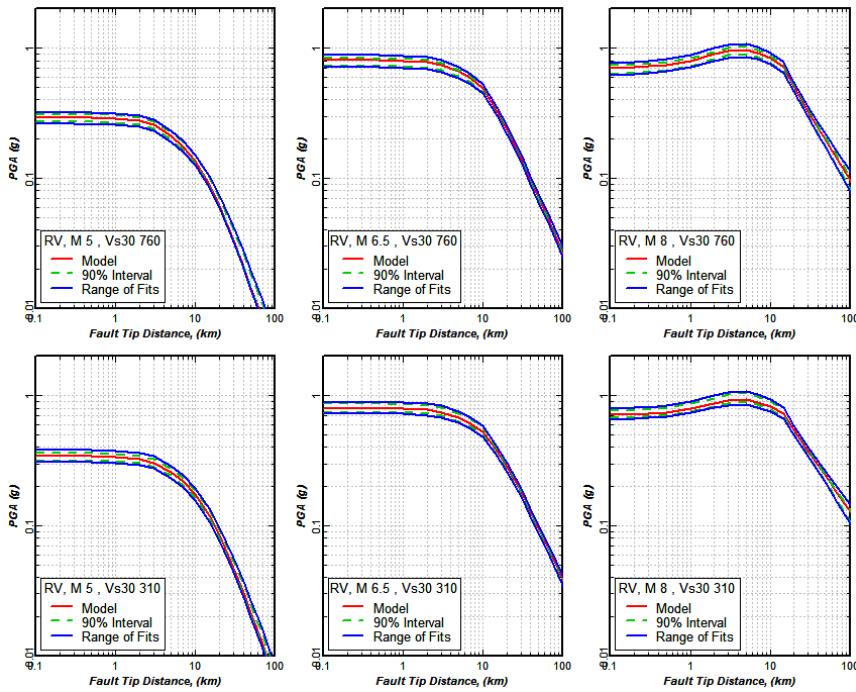

Fig. 7 Uncertainty in $\overline{\ln[PGA(m,r)]}$ for reverse earthquake ground motions due to uncertainty in predictor variables.

Suggested Uncertainty Model(s)

The uncertainties presented above on Figures 2 through 5, combined with the uncertainty resulting from predictor variable uncertainty shown on Figures 6 and 7, provide an estimate of the uncertainty in $\overline{\ln[PGA(m,r)]}$ for the C&Y model. This can be parameterized as a set of (three) alternative median models. Similar calculations can be done for each of the other models, leading to 3×5 ground motion estimation equations. Alternatively, a combined uncertainty across all models could be developed and a reduced number of relationships developed to represent that uncertainty.
